HEMATOLOGY

BASIC PRINCIPLES AND PRACTICE

EIGHTH EDITION

HEMATOLOGY

BASIC PRINCIPLES AND PRACTICE

Ronald Hoffman, MD
Albert A. and Vera G. List Professor of Medicine
Tisch Cancer Institute
Division of Hematology and Medical Oncology
Department of Medicine
Icahn School of Medicine at Mount Sinai
New York, New York

Edward J. Benz, Jr., MD
President and CEO Emeritus, Dana-Farber Cancer Institute
Director and Principal Investigator Emeritus, Dana-Farber/Harvard Cancer Center
Richard and Susan Smith Distinguished Professor of Medicine
Professor of Pediatrics and Genetics
Harvard Medical School
Boston, Massachusetts

Leslie E. Silberstein, MD
Professor of Pathology (Pediatrics)
Harvard Medical School
Director, Joint Program in Transfusion Medicine
Boston Children's Hospital
Brigham and Women's Hospital
Boston, Massachusetts

Helen E. Heslop, MD, DSc (Hon)
Dan L. Duncan Chair
Professor of Medicine and Pediatrics
Director, Center for Cell and Gene Therapy
Baylor College of Medicine
Houston Methodist Hospital and Texas Children's Hospital
Houston, Texas

Jeffrey I. Weitz, MD, FRCP(C), FACP, FRSC
Professor of Medicine and Biochemistry and Biomedical Sciences
McMaster University
Research Chair in Thrombosis
Heart and Stroke Foundation J. F. Mustard Chair in Cardiovascular Research
Executive Director
Thrombosis and Atherosclerosis Research Institute
Hamilton, Ontario, Canada

Mohamed E. Salama, MD
Chief Medical Officer
Sonic Healthcare USA
Austin, Texas

Syed A. Abutalib, MD
Co-Director, Hematology and Cellular Therapy
Director, Clinical Apheresis Programs of Midwest NMDP and Cancer Treatment Centers of America
Part of City of Hope
Zion, Illinois

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

CONTENTS

PART I
MOLECULAR AND CELLULAR BASIS OF HEMATOLOGY 1

1. **Anatomy and Physiology of the Gene 1**
Andrew J. Wagner, Nancy Berliner, and Edward J. Benz, Jr.

2. **Epigenomics in Hematology 16**
Myles Brown and Alok Tewari

3. **Genomic Approaches to Hematology 24**
Gareth J. Morgan and Eileen M. Boyle

4. **Regulation of Gene Expression in Hematology 33**
Stephanie Halene, Toma Tebaldi, and Gabriella Viero

5. **Genome Editing 50**
Matthew Porteus

6. **Signaling Transduction and Metabolomics 59**
Pere Puigserver

7. **Protein Architecture: Relationship of Form and Function 71**
Jia-huai Wang and Michael J. Eck

8. **Pharmacogenomics and Hematologic Diseases 79**
Leo Kager and William E. Evans

PART II
CELLULAR BASIS OF HEMATOLOGY 95

9. **Hematopoietic Stem Cell Biology 95**
Marlies P. Rossmann and John P. Chute

10. **Mitochondria and Hematopoiesis 115**
Luena Papa

11. **Cytokines, Chemokines, Other Growth Factors, and Their Receptors 123**
Hal E. Broxmeyer[†] and Maegan L. Capitano

12. **Role of Chemokines in Leukocyte Trafficking 137**
Antal Rot, Elin Hub, Steffen Massberg, Alexander G. Khandoga, and Ulrich H. von Andrian

13. **Stem Cell Model of Hematologic Diseases 149**
Omar Abdel-Wahab

14. **Hematopoietic Microenvironment 157**
David Scadden and Lev Silberstein

15. **Cell Adhesion 165**
Rodger P. McEver, Pilar Alcaide, and Francis W. Luscinskas

16. **Current Biology of Stem Cell Homing and Mobilization: Dynamic Interactions Between Hematopoietic Stem and Progenitor Cells and Their Surrounding Bone Marrow Microenvironment 174**
Orit Kollet, Montaser Haddad, Priyasmita Chakrabarti, Alejandra Ordonez-Moreno, and Tsvee Lapidot

17. **Control of Cell Division 181**
Martin Fischer and James A. DeCaprio

18. **Cell Death 191**
Paolo Strati, Marina Konopleva, and William Wierda

19. **Aging and Hematopoiesis 201**
Daozheng Yang, Arthur Flohr Svendsen, and Gerald de Haan

PART III
IMMUNOLOGIC BASIS OF HEMATOLOGY 207

20. **Dendritic Cell Biology 207**
Cansu Cimen Bozkus and Nina Bhardwaj

21. **Natural Killer Cell Immunity and Therapy 218**
William E. Carson III

22. **B-Cell Development 231**
Kenneth Dorshkind, Dinesh S. Rao, and David J. Rawlings

23. **Complement and Immunoglobulin Biology Leading to Clinical Translation 242**
David J. Araten, David E. Isenman, and Michael C. Carroll

24. **T-Cell Immunity 271**
Shannon A. Carty, Matthew J. Riese[†], and Gary A. Koretzky

25. **Unmodified Ex Vivo Expanded T Cells 289**
Ifigeneia Tzannou, Wingchi Leung, and Premal Lulla

26. **Treatment of Hematologic Malignancies with Genetically Modified T Cells 295**
Eben I. Lichtman, Malcolm K. Brenner, and Gianpietro Dotti

PART IV
DISORDERS OF HEMATOPOIETIC CELL DEVELOPMENT 303

27. **Biology of Erythropoiesis, Erythroid Differentiation, and Maturation 303**
Thalia Papayannopoulou and Anna Rita Migliaccio

28. **Granulocytopoiesis and Monocytopoiesis 322**
Frederick D. Tsai, Arati Khanna-Gupta, and Nancy Berliner

29. **Thrombocytopoiesis 334**
Camelia Iancu-Rubin and Alan B. Cantor

30. **Inherited Bone Marrow Failure Syndromes 350**
Yigal Dror

31. **Aplastic Anemia 396**
Neal S. Young and Jaroslaw P. Maciejewski

32. **Paroxysmal Nocturnal Hemoglobinuria 416**
David J. Araten and Robert A. Brodsky

33. **Acquired Disorders of Red Cell, White Cell, and Platelet Production 431**
Francis R. LeBlanc, Jaroslaw P. Maciejewski, and Thomas P. Loughran, Jr.

PART V
RED BLOOD CELLS 451

34. **Pathobiology of the Human Erythrocyte and Its Hemoglobins 451**
Martin H. Steinberg, Edward J. Benz, Jr., and Benjamin L. Ebert

35. **Approach to Anemia in the Adult and Child 463**
Judith C. Lin and Edward J. Benz, Jr.

36. **Iron Homeostasis and Its Disorders 473**
Tomas Ganz

37. **Disorders of Iron Homeostasis: Iron Deficiency and Overload 483**
Clara Camaschella

38. **Anemia of Chronic Inflammation 498**
Yelena Z. Ginzburg

39. **Heme Biosynthesis and Its Disorders: Porphyrias and Sideroblastic Anemias 507**
Stephen J. Fuller and James S. Wiley

40. **Megaloblastic Anemias 524**
Aśok C. Antony

41. **Thalassemia Syndromes 555**
Sujit Sheth

42. **Pathobiology of Sickle Cell Disease 585**
Robert P. Hebbel and Gregory M. Vercellotti

43. **Clinical Aspects of Sickle Cell Disease 599**
Laurel A. Menapace and Swee Lay Thein

44. **Hemoglobin Variants Associated with Hemolytic Anemia, Altered Oxygen Affinity, and Methemoglobinemias 630**
Edward J. Benz, Jr. and Benjamin L. Ebert

45. **Red Blood Cell Enzymopathies 638**
Xylina T. Gregg and Josef T. Prchal

46. **Red Blood Cell Membrane Disorders 650**
Patrick G. Gallagher

47. **Autoimmune Hemolytic Anemia 672**
Marc Michel and Ulrich Jäger

48. **Extrinsic Nonimmune Hemolytic Anemias 688**
William C. Mentzer and Stanley L. Schrier†

PART VI
NON-MALIGNANT LEUKOCYTES 698

49. **Neutrophilic Leukocytosis, Neutropenia, Monocytosis, and Monocytopenia 698**
Lawrence Rice, Arthur W. Zieske, and Moonjung Jung

50. **Lymphocytosis, Lymphocytopenia, Hypergammaglobulinemia, and Hypogammaglobulinemia 708**
Sravanti P. Teegavarapu and Martha P. Mims

51. **Disorders of Phagocyte Function 717**
Mary C. Dinauer and Thomas D. Coates

52. **Congenital Disorders of Lymphocyte Function 736**
Sung-Yun Pai and Luigi D. Notarangelo

53. **Pediatric and Adult Histiocytic Disorders 750**
Adi Zoref Lorenz, Olive S. Eckstein, Nitya Gulati, Michael B. Jordan, and Carl E. Allen

54. **Lysosomal Storage Diseases, Focusing on Gaucher Disease: Perspectives and Principles 769**
Atul Mehta, Mia Horowitz, Joaquin Carrillo-Farga, and Ari Zimran

55. **Epstein-Barr Virus and Associated Lymphoproliferative Conditions 782**
Nader Kim El-Mallawany, Lisa R. Forbes, Rayne H. Rouce, and Carl E. Allen

PART VII
HEMATOLOGIC MALIGNANCIES 800

56. **Progress in the Classification of Hematopoietic and Lymphoid Neoplasms: Clinical Implications 800**
Mohamed E. Salama and Ronald Hoffman

57. **Conventional and Molecular Cytogenomic Basis of Hematologic Malignancies 813**
Vesna Najfeld

58. **Pharmacology and Molecular Mechanisms of Antineoplastic Agents for Hematologic Malignancies 900**
Stanton L. Gerson, Paolo F. Caimi, Ehsan Malek, and Benjamin Tomlinson

59. **Pathobiology of Acute Myeloid Leukemia 937**
Andrew M. Brunner and Timothy A. Graubert

60. **Clinical Manifestations and Treatment of Acute Myeloid Leukemia 950**
Harry P. Erba

61. **Myelodysplastic Syndromes 977**
Christopher J. Gibson and David P. Steensma

62. **Allogeneic Hematopoietic Stem Cell Transplantation for Acute Myeloid Leukemia and Myelodysplastic Syndrome in Adults 1001**
John Koreth, Joseph H. Antin, and Corey Cutler

63. **Acute Myeloid Leukemia in Children 1013**
C. Michel Zwaan, Olaf Heidenreich, and E. Anders Kolb

64. **Blastic Plasmacytoid Dendritic Cell Neoplasm 1029**
Andrew A. Lane

65. **Myelodysplastic Syndromes and Myeloproliferative Neoplasms in Children 1036**
Elliot Stieglitz, Christopher C. Dvorak, and Benjamin S. Braun

66. **Pathobiology of Acute Lymphoblastic Leukemia 1049**
Melissa A. Burns, Alejandro Gutierrez, and Lewis B. Silverman

67. **Clinical Manifestations and Treatment of Childhood Acute Lymphoblastic Leukemia 1066**
Rayne H. Rouce and Rachel E. Rau

68. **Acute Lymphoblastic Leukemia in Adults 1078**
Shira Dinner, Sandeep Gurbuxani, Alexandra E. Rojek, Nitin Jain, and Wendy Stock

69. **Chronic Myeloid Leukemia 1103**
Michael W. Deininger

70. **The Polycythemias 1129**
Marina Kremyanskaya, Vesna Najfeld, John Mascarenhas, and Ronald Hoffman

71. **Essential Thrombocythemia 1169**
Bridget K. Marcellino, John Mascarenhas, Camelia Iancu-Rubin, Marina Kremyanskaya, Vesna Najfeld, and Ronald Hoffman

72. **Primary Myelofibrosis and Chronic Neutrophilic Leukemia 1193**
Sangeetha Venugopal, Vesna Najfeld, Alla Keyzner, Siraj M. El Jamal, Ronald Hoffman, and John Mascarenhas

73. **Myelodysplastic Syndrome/Myeloproliferative Neoplasm Overlap Syndromes 1225**
Douglas Tremblay, Jonathan Feld, Nicole Kucine, Noa Rippel, Siraj M. El Jamal, and John Mascarenhas

74. **Eosinophilia, Eosinophilic Neoplasms, and the Hypereosinophilic Syndromes 1243**
Peter Valent, Andreas Reiter, and Jason Gotlib

75. **Mast Cells and Mastocytosis 1263**
Jason Gotlib, Hans-Peter Horny, and Peter Valent

76. **Chronic Lymphocytic Leukemia 1282**
Farrukh T. Awan and John C. Byrd

77. **Hairy Cell Leukemia 1301**
Farhad Ravandi

78. **The Pathologic Basis for the Classification of Non-Hodgkin and Hodgkin Lymphomas 1314**
Girish Venkataraman, Elaine S. Jaffe, and Stefania Pittaluga

79. **Origin of Hodgkin Lymphoma and Therapeutic Targets 1331**
Ralf Küppers

80. **Hodgkin Lymphoma 1339**
Anas Younes, Ann S. LaCasce, Graham Collins, Bouthaina Dabaja, and Ahmet Dogan

81. **Origin of Non-Hodgkin Lymphoma and Therapeutic Targets 1352**
Matthew S. McKinney and Sandeep S. Dave

82. **Clinical Manifestations, Staging, and Treatment of Follicular Lymphoma 1367**
Lucy Pickard and John G. Gribben

83. **Marginal Zone Lymphomas (Extranodal/MALT, Splenic, and Nodal) 1378**
Samer Al Hadidi and Carlos A. Ramos

84. **Diffuse Large B-Cell Lymphoma of the Central Nervous System 1390**
Syed A. Abutalib, Nilanjan Ghosh, Alexander Feldman†, Karan S. Dixit, and Rimas V. Lukas

85. **High-Grade B-Cell Lymphomas 1420**
Kieron Dunleavy and Stephen Douglas Smith

86. **Mantle Cell Lymphoma 1430**
Julie M. Vose

87. **Virus-Associated Lymphoma 1439**
Katherine C. Rappazzo, Jennifer A. Kanakry, and Richard F. Ambinder

88. **Malignant Lymphomas in Childhood 1448**
Kara M. Kelly, Birgit Burkhardt, and Catherine M. Bollard

89. **T-Cell Lymphomas 1462**
Alessandro Broccoli and Pier Luigi Zinzani

90. **Monoclonal Gammopathy of Undetermined Significance and Smoldering Multiple Myeloma 1492**
S. Vincent Rajkumar and Shaji Kumar

91. **Multiple Myeloma 1506**
Sydney X. Lu, Even H. Rustad, Saad Z. Usmani, and C. Ola Landgren

92. **Waldenström Macroglobulinemia/Lymphoplasmacytic Lymphoma 1539**
Jorge J. Castillo and Steven P. Treon

93. **Immunoglobulin Light-Chain Amyloidosis (Primary Amyloidosis) 1553**
Morie A. Gertz, Francis K. Buadi, Martha Q. Lacy, and Suzanne R. Hayman

PART VIII

COMPREHENSIVE CARE OF PATIENTS WITH HEMATOLOGIC MALIGNANCIES 1567

94. **Key Considerations for Managing Infections in the Compromised Host 1567**
Samuel A Shelburne, Russell E. Lewis, and Dimitrios P. Kontoyiannis

95. **Principles of Radiation Therapy for Hematologic Disease 1583**
Idalid Franco, Daphne Haas-Kogan, and Andrea K. Ng

96. **Grading and Toxicity Management after Immune Effector Therapy 1594**
Emily C. Ayers, Noelle V. Frey, and Daniel W. Lee

97. **Identification and Management of Checkpoint Inhibition Toxicity 1599**
Evgeniya Kharchenko and John W. Sweetenham

98. **Psychosocial Aspects of Hematologic Disorders 1605**
Hermioni L. Amonoo, Cynthia S. Peng, Rebecca M. Hammond, and Roxanne Sholevar

99. **Pain Management and Antiemetic Therapy in Hematologic Disorders 1616**
Thomas W. LeBlanc

100. **Palliative Care 1631**
Kathleen A. Lee, Hilary McGuire, Barbara Reville, and Janet L. Abrahm

101. **Therapy-related Late Effects of Hematologic Malignancies 1638**
Wendy Landier and Smita Bhatia

PART IX

TRANSPLANTATION AND OTHER CELL-BASED THERAPIES 1653

102. **Practical Aspects of Hematopoietic Stem Cell Harvesting and Mobilization 1653**
Abba C. Zubair and Scott D. Rowley

103. **Graft Engineering and Cell Processing 1667**
Adrian P. Gee

104. **Principles of Cell-Based Genetic Therapies 1679**
David A. Williams

105. **Indications, Outcomes, and Donor Selection for Allogeneic Hematopoietic Cell Transplantation for Hematologic Malignancies in Adults 1689**
Saurabh Chhabra, Mehdi Hamadani, and Parameswaran N. Hari

106. **Unrelated Donor Hematopoietic Cell Transplantation 1703**
Effie Wang Petersdorf and Katharine Hsu

107. **Haploidentical Hematopoietic Stem Cell Transplantation 1713**
Stefan O. Ciurea

108. **Cord Blood Transplantation 1732**
Joseph E. Maakaron, Najla El-Jurdi, and Claudio G. Brunstein

109. **Graft-versus-Host Disease and Graft-versus-Leukemia Responses 1749**
Mary Riwes, James L. Ferrara, Pavan Reddy, and John M. Magenau

110. **Supportive Care for the Transplant Patient 1770**
Abraham S. Kanate and Navneet S. Majhail

PART X

TRANSFUSION MEDICINE 1785

111. **Human Blood Group Antigens and Antibodies 1785**
William J. Lane, Connie M. Westhoff, Jill R. Storry, and Beth H. Shaz

112. **Principles of Red Blood Cell Transfusion 1801**
Robert A. DeSimone, Paul M. Ness, and Melissa M. Cushing

113. **Clinical Considerations in Platelet Transfusion Therapy 1814**
Richard M. Kaufman

114. **Human Leukocyte Antigen and Human Neutrophil Antigen Systems 1820**
Ena Wang, Sharon Adams, David F. Stroncek, and Francesco M. Marincola

115. **Principles of Plasma and Plasma Derivatives 1837**
Alexandra Jimenez, Christopher D. Hillyer, and Beth H. Shaz

116. **Hemapheresis 1852**
Kamille A. West and Harvey G. Klein

117. **Transfusion Reactions to Blood and Hematopoietic Stem Cell Therapy Products 1864**
Martin R. Schipperus and Johanna C. Wiersum-Osselton

118. **Transfusion-Transmitted Diseases 1874**
Lauren A. Crowder and Susan L. Stramer

119. **Pediatric Transfusion Medicine 1892**
Bentley B. Rodrigue and Steven R. Sloan

120. **Transfusion and Apheresis Support for Sickle Cell Disease Patients 1900**
John P. Manis

PART XI

HEMOSTASIS AND THROMBOSIS 1906

121. **Overview of Hemostasis and Thrombosis 1906**
James C. Fredenburgh and Jeffrey I. Weitz

122. **Blood Vessels 1919**
Aly Karsan and Janusz Rak

123. **Megakaryocyte and Platelet Structure 1937**
Kellie R. Machlus and Joseph E. Italiano, Jr.

124. **Molecular Basis of Platelet Function 1950**
Margaret L. Rand and Sara J. Israels

125. **Molecular Basis of Blood Coagulation 1968**
Kathleen Brummel-Ziedins, Kenneth G. Mann, James C. Fredenburgh, and Jeffrey I. Weitz

126. **Evaluation of the Patient with Suspected Bleeding Disorders 1988**
Catherine P. M. Hayward and Alice D. Ma

127. **Laboratory Evaluation of Hemostatic and Thrombotic Disorders 1996**
Menaka Pai and Karen A. Moffat

128. **Acquired Disorders of Platelet Function 2007**
Peter L. Gross and José A. López

129. **Diseases of Platelet Number: Immune Thrombocytopenia, Neonatal Alloimmune Thrombocytopenia, and Posttransfusion Purpura 2020**
Michelle P. Zeller, Shuoyan Ning, Donald M. Arnold, and Caroline Gabe

130. **Thrombocytopenia Caused by Hypersplenism, Platelet Destruction, or Surgery/Hemodilution 2033**
Theodore E. Warkentin

131. **Heparin-Induced Thrombocytopenia 2049**
Theodore E. Warkentin

132. **Thrombotic Thrombocytopenic Purpura and the Hemolytic Uremic Syndromes 2063**
Gemlyn George and Kenneth D. Friedman

133. **Structure, Biology, and Genetics of von Willebrand Factor 2081**
Paula James, Orla Rawley, and Mackenzie Bowman

134. **Hemophilia A and B 2095**
Manuel Carcao, Keith Gomez, Davide Matino, and Glenn F. Pierce

135. **Rare Coagulation Factor Deficiencies 2125**
David Gailani, Benjamin F. Tillman, and Allison P. Wheeler

136. **Transfusion Therapy for Coagulation Factor Deficiencies 2144**
Elizabeth Roman and Catherine S. Manno

137. **Disseminated Intravascular Coagulation 2156**
Marcel Levi

138. **Hypercoagulable States 2167**
Julia A. M. Anderson and Jeffrey I. Weitz

139. **Antiphospholipid Syndrome 2179**
Lucia R. Wolgast and Jacob H. Rand

140. **Venous Thromboembolism 2196**
Noel C. Chan and Jeffrey I. Weitz

141. **Prevention and Treatment of Venous Thromboembolism in Pregnancy 2205**
Leslie Skeith and Shannon M. Bates

142. **Atherothrombosis 2212**
Daisy Sahoo, Moua Yang, and Roy L. Silverstein

143. **Antithrombotic Drugs 2223**
Iqbal H. Jaffer and Jeffrey I. Weitz

144. **Stroke 2241**
Emer Mcgrath, Michelle Canavan, and Martin O'Donnell

145. **Acute Coronary Syndromes 2251**
John W. Eikelboom and Jeffrey I. Weitz

146. **Peripheral Artery Disease 2261**
Stanislav Henkin and Mark A. Creager

147. **Atrial Fibrillation 2270**
Monika Kozieł Siołkowska, Tatjana S. Potpara, and Gregory Y. H. Lip

148. **Bleeding and Clotting Disorders in Pediatrics 2278**
Nasrin Samji, Anthony K. C. Chan, and Mihir D. Bhatt

PART XII
CONSULTATIVE HEMATOLOGY 2292

149. **Hematologic Changes in Pregnancy 2292**
Arielle L. Langer, Michael Paidas, and Caroline Cromwell

150. **Hematologic Manifestations of End-Organ Failure 2305**
Marissa Laureano and Christopher Hillis

151. **Hematologic Manifestations of Solid Tumors 2312**
Kathryn DeCarli, Peter Barth, Andrew M. Brunner, and Fred J. Schiffman

152. **Hematologic Manifestations of HIV/AIDS 2319**
Maryam Own and James B. Bussel

153. **Hematologic Findings and Consequences of Novel Coronavirus (SARS-CoV-2) Infection 2335**
Leonard Naymagon and Douglas Tremblay

154. **Hematologic Aspects of Parasitic Diseases 2342**
David J. Roberts

155. **Hematologic Problems in the Surgical Patient: Bleeding and Thrombosis 2369**
Iqbal H. Jaffer and Jeffrey I. Weitz

156. **The Spleen and Its Disorders 2378**
Thomas A. Ollila, Adam S. Zayac, and Fred J. Schiffman

157. **Aging and Hematologic Disorders 2394**
Kah Poh Loh, Mazie Tsang, Shakira J. Grant, Richard J. Lin, and Heidi D. Klepin

158. **Onco-cardiology: Focus on Cardiac Complications of Hematologic Treatments 2400**
Andrea Gallardo-Grajedau and Gagan Sahni

159. **Resources for the Hematologist: Interpretive Comments and Selected Reference Values for Neonatal, Pediatric, and Adult Populations 2408.e1**
Andrea N. Marcogliese and Lisa Hensch

PART I MOLECULAR AND CELLULAR BASIS OF HEMATOLOGY

CHAPTER 1

ANATOMY AND PHYSIOLOGY OF THE GENE

Andrew J. Wagner, Nancy Berliner, and Edward J. Benz, Jr.

Normal blood cells have limited life spans; they must be replenished in precise numbers by a continuously renewing population of progenitor cells. Homeostasis of the blood requires that proliferation of these cells be efficient yet strictly constrained. Many distinctive types of mature blood cells must arise from these progenitors by a controlled process of commitment to, and execution of, complex programs of differentiation. Thus developing red blood cells must produce large quantities of hemoglobin but not the myeloperoxidase characteristic of granulocytes, the immunoglobulins characteristic of lymphocytes, or the fibrinogen receptors characteristic of platelets. Similarly, the maintenance of normal amounts of procoagulant and anticoagulant proteins in the circulation requires an exquisitely regulated production, destruction, and interaction of the components. Understanding the basic biologic principles underlying cell growth, differentiation, death, and the homeostasis of critical proteins requires a thorough knowledge of the structure and regulated expression of genes because the gene is now known to be the fundamental unit by which biologic information is stored, transmitted, and expressed in this regulated fashion.

Genes were originally characterized as mathematic units of inheritance. They are now known to consist of molecules of deoxyribonucleic acid (DNA). By virtue of their ability to store information in the form of nucleotide sequences, to transmit it by means of semiconservative replication to daughter cells during mitosis and meiosis, and to express it by directing the incorporation of amino acids into proteins, DNA molecules are the chemical transducers of genetic information flow. Efforts to understand the biochemical means by which this transduction is accomplished have given rise to the disciplines of molecular biology and molecular genetics.

THE GENETIC VIEW OF THE BIOSPHERE: THE CENTRAL DOGMA OF MOLECULAR BIOLOGY

The fundamental premise of the molecular biologist is that the magnificent diversity encountered in nature is ultimately governed by genes. The capacity of genes to exert this control is in turn determined by relatively simple stereochemical rules, first appreciated by Watson and Crick in the 1950s. These rules govern the types of interactions that can occur between two molecules of DNA or ribonucleic acid (RNA).

DNA and RNA are linear unbranched polymers consisting of four types of nucleotide subunits. Each nucleotide is distinguished from the others by a unique purine or pyrimidine "base" projecting from the chain. Proteins are linear unbranched polymers consisting of 21 types of amino acid subunits. Each amino acid is distinguished from the others by the chemical nature of its side chain, the moiety not involved in forming the peptide bond links of the chain. The properties of cells, tissues, and organisms depend largely on the aggregate structures, properties and biochemical activities of their proteins, and the interactions occurring among them. The central dogma of molecular biology states that genes control these properties by encoding the structures of proteins, controlling the timing and amount of their production, and coordinating their synthesis with that of other proteins. The information needed to achieve these ends is transmitted (expressed) from DNA and translated into proteins by a class of nucleic acid molecules called RNA. Genetic information thus flows in the direction DNA → RNA → protein. This central dogma provides, in principle, a universal approach for investigating the biologic properties and behavior of any given cell, tissue, or organism by study of the controlling genes. Methods permitting direct manipulation of DNA and RNA sequences should then be universally applicable to the study of all living entities. Indeed, the power of the methodologies of molecular genetics lie in the universality of their utility.

One exception to the central dogma of molecular biology that is especially relevant to hematologists is the storage of genetic information in RNA molecules in certain viruses, notably the retroviruses associated with T-cell leukemia and lymphoma, and the human immunodeficiency virus. When retroviruses enter the cell, the RNA genome (the term "genome" refers to the totality of DNA or RNA sequences encoding the genetic information of a cell, tissue, or organism) is copied into a DNA replica (cDNA). This is accomplished with RNA-dependent DNA polymerases, enzymes also called *reverse transcriptases*. This DNA representation of the viral genome is then expressed according to the pathway specified by the central dogma. Retroviruses thus represent a variation on the theme rather than a true exception to or violation of the dogma. There are also some RNA viruses (coronaviruses being the most universally known example) that carry an RNA-dependent RNA polymerase capable of replicating many copies of its own RNA genome. These messenger RNAs (mRNAs) then encode proteins essential to their life cycle.

THE ANATOMY AND PHYSIOLOGY OF THE GENE

DNA and RNA Structure

DNA molecules are extremely long, unbranched polymers of nucleotide subunits. Each nucleotide contains a sugar moiety called deoxyribose, a phosphate group attached to the 5′ carbon position, and a purine or pyrimidine base attached to the 1′ position (Fig. 1.1). The linkages in the chain are formed by phosphodiester bonds between the 5′ position of each sugar residue and the 3′ position of the adjacent residue in the chain (see Fig. 1.1). The sugar-phosphate links

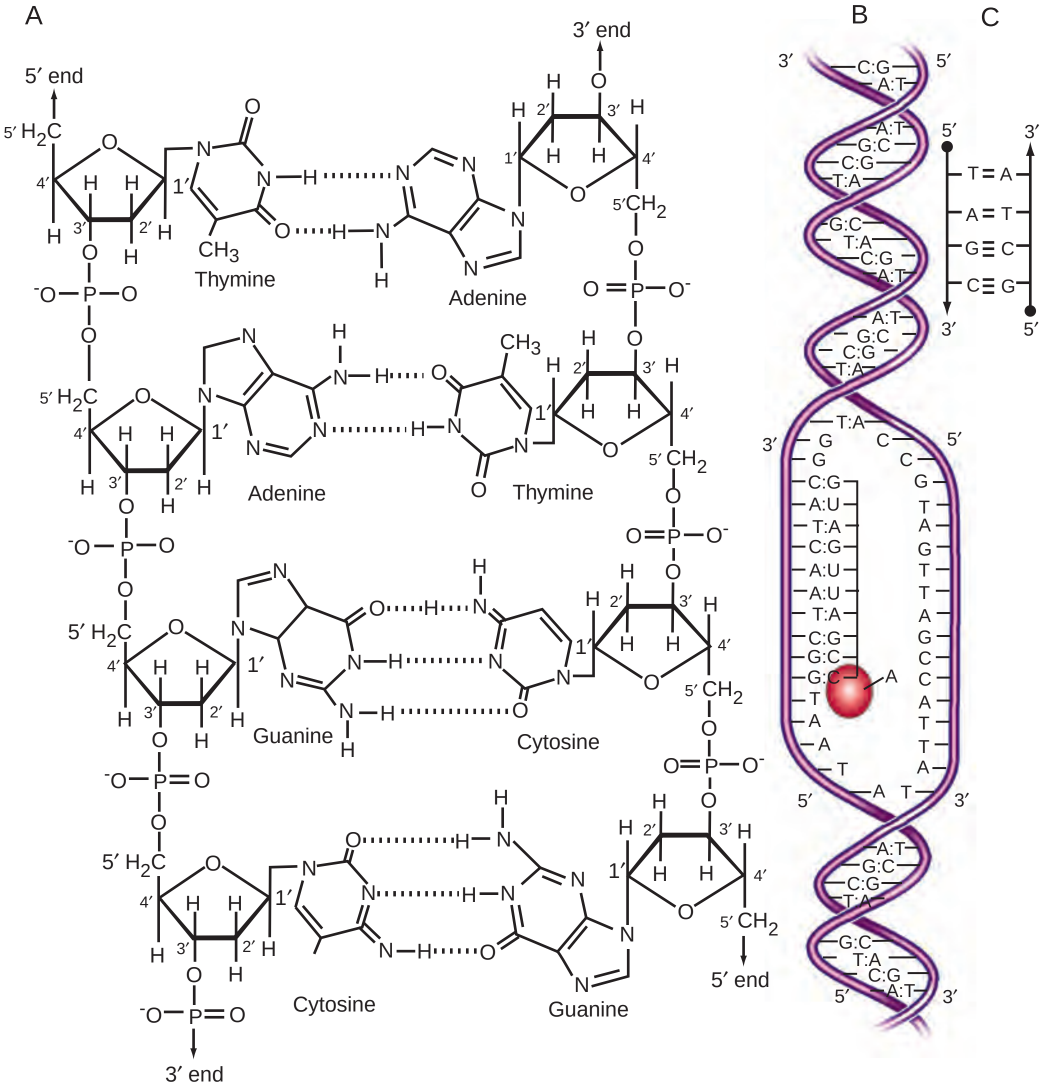

Figure 1.1 STRUCTURE, BASE PAIRING, POLARITY, AND TEMPLATE PROPERTIES OF DNA. (A) Structures of the four nitrogenous bases projecting from sugar phosphate backbones. The hydrogen bonds between them form base pairs holding complementary strands of DNA together. Note that A–T and T–A base pairs have only two hydrogen bonds, whereas C–G and G–C pairs have three. (B) The double helical structure of DNA results from base pairing of strands to form a double-stranded molecule with the backbones on the outside and the hydrogen-bonded bases stacked in the middle. Also shown schematically is the separation (unwinding) of a region of the helix by mRNA polymerase, which is shown using one of the strands as a template for the synthesis of an mRNA precursor molecule. Note that new bases added to the growing RNA strand obey the rules of Watson-Crick base pairing (see text). Uracil (U) in RNA replaces T in DNA and, like T, forms base pairs with A. (C) Diagram of the antiparallel nature of the strands, based on the stereochemical 3′ → 5′ polarity of the strands. The chemical differences between reading along the backbone in the 5′ → 3′ and 3′ → 5′ directions can be appreciated by reference to (A). *A*, Adenosine; *C*, cytosine; *G*, guanosine; *T*, thymine; *U*, uracil.

form the backbone of the polymer, from which the purine or pyrimidine bases project perpendicularly.

The haploid human genome consists of 23 long, double-stranded DNA molecules tightly complexed with histones and other nuclear proteins to form compact linear structures called *chromosomes*. The genome contains approximately 3 billion nucleotides; the individual chromosomes range from 50 to 200 million bases in length. By convention they are numbered from the longest (chromosome 1) to the shortest (chromosome 22), with the sex chromosomes getting the special designation X and Y. Females inherit the XX genotype and males, XY. The individual genes are aligned along each chromosome. The human genome contains about 2000 to 30,000 genes. Blood cells, like most somatic cells, are diploid. That is, each chromosome is present in two copies, so there are 46 chromosomes consisting of approximately 6 billion base pairs (bp) of DNA.

The four nucleotide bases in DNA are two purines (adenosine and guanosine) and two pyrimidines (thymine and cytosine). The basic chemical configuration of the other nucleic acid found in cells, RNA, is quite similar, except that the sugar is ribose (having a hydroxyl group attached to the 2′ carbon rather than the hydrogen found in deoxyribose) and the pyrimidine base uracil is used in place of thymine. The bases are commonly referred to by a shorthand notation: the letters A, C, G, T, and U are used to refer to adenosine, cytosine, guanosine, thymine, and uracil, respectively.

The ends of DNA and RNA strands are chemically distinct because of the 3′ → 5′ phosphodiester bond linkage that ties adjacent bases together (see Fig. 1.1). One end of the strand (the 3′ end) has an unlinked (free at the 3′ carbon) sugar position, and the other (the 5′ end) has a free 5′ position. There is thus a directionality (polarity) to the sequence of bases in a DNA strand: the same sequence of bases read in a 3′ → 5′ direction carries a different meaning than if read in a 5′ → 3′ direction. Cellular enzymes can thus distinguish one end of a nucleic acid from the other and one strand from its paired mate; most enzymes that "read" the DNA sequence tend to do so only in one direction (3′ → 5′ or 5′ → 3′ but not both). For instance, most nucleic acid–synthesizing enzymes read the template strand in 3′ → 5′ direction, thus adding new bases to the strand in a 5′ → 3′ direction.

Storage of Genetic Information in the Nucleotide Sequences of DNA

The ability of DNA molecules to store information resides in the sequence of nucleotide bases arrayed along the polymer chain. Under the physiologic conditions in living cells, DNA is thermodynamically most stable when two strands coil around each other to form a double-stranded helix. The strands are aligned in an "antiparallel" direction, having opposite 3′ → 5′ polarities (see Fig. 1.1). The DNA strands are held together by hydrogen bonds between the bases on one strand and the bases on the opposite (complementary) strand. The stereochemistry of these interactions allows bonds to form between the two strands only when adenine on one strand pairs with thymine at the same position of the opposite strand, or guanine with cytosine. These are the "Watson-Crick" rules of base pairing. Two strands joined together in compliance with these rules are said to have "complementary" base sequences. Similar rules apply to the formation of DNA-RNA or RNA-RNA double-stranded hybrids, except that A-U base pairs replace A-T pairs.

These thermodynamic rules imply that the sequence of bases along one DNA strand immediately dictates the sequence of bases that must be present along the complementary strand in the double helix. For example, whenever an A occurs along one strand, a T must be present at that exact position on the opposite strand; a G must always be paired with a C, a T with an A, and a C with a G.

Single-stranded nucleic acids can also fold back on themselves if two complementary sequences exist at different points along the molecule, thus forming "hairpin loops." Hairpin loop structures create secondary structures that affect the accessibility of sequences and the interaction of the molecule with proteins or other nucleic acids.

Transmission of Genetic Information to the Next Generation

Enzymes that replicate (polymerize) DNA and RNA molecules obey the base-pairing rules. By using an existing strand of DNA or RNA as the template, a new (daughter) strand is copied (transcribed) by reading processively along the base sequence of the template strand, adding to the growing strand at each position only that base that is complementary to the corresponding base in the template according to the Watson-Crick rules. Thus a DNA strand having the base sequence 5′-GGCTATG-3′ could be copied by DNA polymerase only into a daughter strand having the sequence 3′-CCGATAC-5′. Note that the sequence of the template strand provides all the information needed to predict the nucleotide sequence of the complementary daughter strand. Genetic information is thus stored in the form of base-paired nucleotide sequences.

If a double-stranded DNA molecule is separated into its two component strands and each strand is then used as a template to synthesize a new daughter strand, the product will be two double-stranded daughter DNA molecules, each identical to the original parent molecule. This semiconservative replication process is exactly what occurs during mitosis and meiosis as cell division proceeds (Fig. 1.2). The rules of Watson-Crick base pairing thus provide for the faithful transmission of exact copies of the cellular genome to subsequent generations.

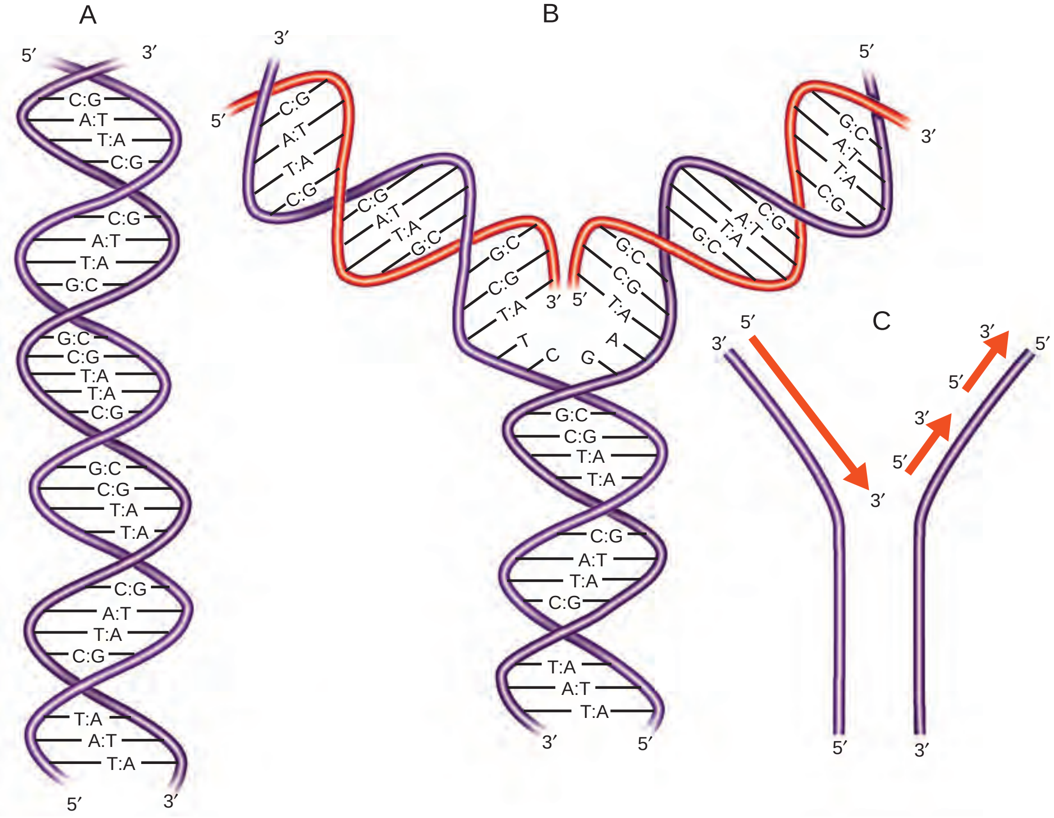

Figure 1.2 SEMICONSERVATIVE REPLICATION OF DNA. (A) The process by which the DNA molecule on the left is replicated into two daughter molecules, as occurs during cell division. Replication occurs by separation of the parent molecule into the single-stranded form at one end, reading of each of the daughter strands in the 3′ → 5′ direction by DNA polymerase, and addition of new bases to growing daughter strands in the 5′ → 3′ direction. (B) The replicated portions of the daughter molecules are identical to each other *(red)*. Each carries one of the two strands of the parent molecule, accounting for the term *semiconservative replication*. Note the presence of the replication fork, the point at which the parent DNA is being unwound. (C) The antiparallel nature of the DNA strands demands that replication proceed toward the fork in one direction and away from the fork in the other *(red)*. This means that replication is actually accomplished by reading of short stretches of DNA followed by ligation of the short daughter strand regions to form an intact daughter strand.

The Expression of Genetic Information Via Translation Into Proteins Using the Genetic Code

The information stored in the DNA base sequence of genes achieves its impact on the structure, function, and behavior of organisms by governing the structures, timing, and amounts of proteins and certain RNAs synthesized in the cells. The primary structure (i.e., the amino acid sequence) of each protein determines its three-dimensional conformation and therefore its properties (e.g., shape, enzymatic activity, ability to interact with other molecules, localization, and stability). In the aggregate, these proteins control cell structure and metabolism. The process by which DNA achieves its control of cells through protein synthesis is called *gene expression*.

An outline of the basic pathway of gene expression in eukaryotic cells is shown in Fig. 1.3. The DNA base sequence of the "minus," "anticoding" strand is first copied into an RNA molecule with a complementary base sequence, called *premessenger RNA* (pre-mRNA), by mRNA polymerase. Pre-mRNA thus has a base sequence identical to

Figure 1.3 SYNTHESIS OF mRNA AND PROTEIN—THE PATHWAY OF GENE EXPRESSION. The diagram of the DNA gene shows the alternating array of exons *(red)* and introns *(shaded color)* typical of most eukaryotic genes. Transcription of the mRNA precursor, addition of the 5′-CAP and 3′-poly (A) tail, splicing and excision of introns, transport to the cytoplasm through the nuclear pores, translation into the amino acid sequence of the apoprotein, and posttranslational processing of the protein are described in the text. Translation proceeds from the initiator methionine codon near the 5′ end of the mRNA, with incorporation of the amino terminal end of the protein. As the mRNA is read in a 5′ → 3′ direction, the nascent polypeptide is assembled in an amino → carboxyl terminal direction.

the DNA "plus" or "coding" strand. Genes in eukaryotic species consist of tandem arrays of sequences encoding mature mRNA (exons) alternating with sequences (introns) present in the initial mRNA transcript (pre-mRNA) but absent from the mature mRNA. The entire gene is transcribed into the larger precursor, which is then further processed (spliced) in the nucleus. The introns are excised from the final mature mRNA molecule, which is then further processed, as discussed later, and exported to the cytoplasm to be decoded (translated) into the amino acid sequence of the protein by association with a biochemically complex group of ribonucleoprotein structures called *ribosomes*. Ribosomes contain two subunits: the 60 S subunit contains a single, large (28 S) ribosomal RNA (rRNA) molecule complexed with multiple proteins, and the 40 S subunit. The RNA component of the 40 S subunit is a smaller (18 S) rRNA.

Ribosomes read an mRNA sequence in a ticker tape fashion three bases at a time, inserting the appropriate amino acid encoded by each three-base code word or codon into the appropriate position of the growing protein chain. This process is called *mRNA translation*. The glossary used by cells to know which amino acids are encoded by each DNA codon is called the *genetic code* (Table 1.1). Each amino acid is encoded by a sequence of three successive bases. Because there are four code letters (A, C, G, and U) and because sequences read in the 5′ → 3′ direction have a different biologic meaning than sequences read in the 3′ → 5′ direction, there are 4^3, or 64, possible codons consisting of three bases.

There are 21 naturally occurring amino acids found in proteins. Thus more codons are available than amino acids to be encoded. As noted in Table 1.1, a consequence of this redundancy is that some amino acids are encoded by more than one codon. For example, six distinct codons can specify incorporation of arginine into a growing amino acid chain, four codons can specify valine, two can specify glutamic acid, and only one each methionine or tryptophan. However, in no case does a single codon encode more than one amino acid. Codons thus predict unambiguously the amino acid sequence they encode. In contrast, one cannot easily read backward from the amino acid sequence to decipher the *exact* encoding DNA sequence. These facts are summarized by saying that the code is degenerate but not ambiguous.

Some specialized codons serve as punctuation points during translation. The methionine codon (AUG), when surrounded by a consensus nucleotide sequence motif (the Kozak box) near the beginning (5′ end) of the mRNA, serves as the initiator codon signaling the first amino acid to be incorporated. All proteins initially begin with a methionine residue, but this is often removed later in the translational process. Three codons, UAG, UAA, and UGA, serve as translation terminators, signaling the end of translation.

The adaptor molecules mediating individual decoding events during mRNA translation are small (40 bases long) RNA molecules called *transfer RNAs* (tRNAs). When bound into a ribosome, each tRNA exposes a three-base segment within its sequence called the *anticodon*. These three bases attempt to pair with the three-base codon exposed on the mRNA. If the anticodon is complementary in sequence to the codon, a stable interaction among the mRNA, the ribosome, and the tRNA molecule results. Each tRNA also contains a separate region that is adapted for covalent binding to an amino acid. The enzymes that catalyze the binding of each amino acid are constrained in such a way that each tRNA species can bind only to a single amino acid. For example, tRNA molecules containing the anticodon 3′-AAA-5′, which is complementary to a 5′-UUU-3′ (phenylalanine) codon in mRNA, can be bound to or charged with only phenylalanine; tRNA containing the anticodon 3′-UAG-5′ can be charged with only isoleucine, and so forth.

tRNAs and their amino acyl tRNAs transduce nucleic acid information into the amino acid sequence that determines it physiologic properties. Ribosomes provide the structural matrix on which tRNA anticodons and mRNA codons become properly exposed and aligned in an orderly, linear, and sequential fashion. As each new codon is exposed, the appropriate charged tRNA species is bound. A peptide bond is then formed between the amino acid carried by this tRNA and the C-terminal residue on the existing nascent protein chain. The growing chain is transferred to the new tRNA in the process, so that it is held in place as the next tRNA is brought in. This cycle is repeated until completion of translation. The completed polypeptide is then transferred to other organelles for further processing (e.g., to the endoplasmic reticulum and the Golgi apparatus) or released into the cytosol for association with other subunits to form complex multimeric proteins (e.g., hemoglobin) and so forth, as discussed in Chapters 4 and 7.

TABLE 1.11 **The Genetic Code[a] Messenger RNA Codons for the Amino Acids**

REGULATION OF GENE EXPRESSION

Virtually all cells of an organism receive a complete copy of the DNA genome inherited at the time of conception. The diversity of distinct cell types and tissues found in any complex organism is possible only because different portions of the genome are selectively expressed or repressed in each cell type. Each cell must "know" which genes to express, how actively to express them, and when to express them. This biologic necessity has come to be known as *gene regulation* or *regulated gene expression*. Understanding gene regulation provides insight into how pluripotent stem cells determine that they will express the proper sets of genes in daughter progenitor cells that differentiate along each lineage. Major hematologic disorders (e.g., the leukemias and lymphomas), immunodeficiency states, and myeloproliferative syndromes result from derangements in the system of gene regulation. An understanding of the ways that genes are selected for expression thus remains one of the major frontiers of biology and medicine. Chapters 2, 4, and 6 offer a more thorough coverage of these topics. The following sections provide brief introductions.

Chromatin and the Epigenetic Regulation of Gene Expression

Only a small fraction of the 6 billion base pairs of DNA present in a diploid human cell codes for proteins or for the ribosomal, transfer, and spliceosome RNAs, even including the nearby DNA sequences (promoters, repressors, enhancers, silencers, and insulator sequences) that are needed to support regulated protein synthesis. As discussed later and in Chapter 4, many additional species of RNA molecules exhibiting important regulatory effects on gene expression have been and still are being discovered. Yet, less than 10% of the genome accounts for all DNA sequences having a known function in gene expression. The remainder is called "DNA dark matter." It is being intensively investigated, but its purpose and impact on homeostasis remain unknown. A major challenge for cells, then, is how to find the genes and how to identify and activate only those genes whose expression it needs for its vital functions. The field of study that has arisen to address these questions is called epigenetics. This section provides only a brief introduction to epigenetics; Chapter 2 offers a thorough review and documents the increasing importance of epigenetics to hematology.

Most of the DNA in living cells is inactivated by formation of a nucleoprotein complex called *chromatin*. The histone and nonhistone proteins in chromatin effectively sequester genes from enzymes needed for expression. The most tightly compacted chromatin regions are called *heterochromatin*. *Euchromatin*, less tightly packed, contains actively transcribed genes. Activation of a gene for expression (i.e., transcription) requires that it become less compacted and more accessible to the transcription apparatus. These processes involve both *cis*-acting and *trans*-acting factors. *Cis*-acting elements are regulatory DNA sequences within or flanking the genes. They are recognized by *trans*-acting factors, which are nuclear DNA–binding proteins needed for transcriptional regulation.

DNA sequence regions flanking genes are called *cis*-acting because they influence expression of nearby genes only on the same chromosome. These sequences do not usually encode mRNA or protein molecules. They alter the conformation of the gene within chromatin twisting or kinking the surrounding DNA in ways that facilitate or inhibit access to the factors that modulate transcription. When exogenous nucleases (DNAses) are added experimentally in small amounts to nuclei, these exposed regions are especially sensitive to their DNA-cutting action. Thus DNAse hypersensitive sites in chromatin have come to be useful as markers for regions in or near genes that are accessible for transcription (Chapter 2).

DNA methylation is an epigenetic structural feature that also marks differences between actively transcribed and inactive genes. Most eukaryotic DNA is heavily methylated; that is, the DNA is modified by the addition of a methyl group to the 5 position of the cytosine pyrimidine ring (5-methyl-C). In general, heavily methylated genes are inactive; active genes are relatively hypomethylated, especially in the 5′ and 3′ flanking regions containing the promoter and other regulatory elements (see "Enhancers, Promoters, and Silencers"). These flanking regions frequently include DNA sequences with a high content of Cs and Gs (CpG islands). Hypomethylated CpG islands serve as markers of actively transcribed genes. For example, a search for undermethylated CpG islands on chromosome 7 facilitated the search for the gene for cystic fibrosis.

DNA methylation is facilitated by DNA methyltransferases (DMTs). DNA replication incorporates unmethylated nucleotides into each nascent strand, thus leading to demethylated DNA. For cytosines to become methylated, the methyltransferases must act after each round of replication. After an initial wave of demethylation early in embryonic development, regulatory elements are methylated during various stages of development and differentiation (Chapter 2). Aberrant DNA methylation also occurs as an early step during tumorigenesis, leading to silencing of tumor suppressor genes and of genes related to differentiation. This finding has led to induction of DNA demethylation as a target in cancer therapy. Indeed, 5-azacytidine, a cytidine analog that inhibits DMT, and the related compound decitabine, are approved by the US Food and Drug Administration (FDA) for use in myelodysplastic syndromes, and their use in cases of other malignancies is being investigated.

The mechanisms by which particular regions of DNA are targeted for methylation are under intense investigation. It is becoming increasingly apparent that this modification begets further alterations in chromatin proteins that in turn influence gene expression.

The "opening" of chromatin is necessary but not sufficient for genes to be expressed. The sequences within the now-accessible regions of DNA that are intended for transcription, and no others, must be identified and configured for binding by the intranuclear factors and mRNA polymerase that will execute the transcription program. This is accomplished by the presence of sequences embedded near or within the gene that are recognized by specific proteins that activate or inactivate transcription depending on which stimulatory or inhibitory proteins the sequences attract. These are discussed in the next section.

The major protein components of chromatin are histones, which are a small, highly basic protein family that binds tightly to the acidic residues in DNA. Histones can be acetylated, reducing their affinity for DNA, or methylated, which stabilizes their binding. Histone acetylation, phosphorylation, and methylation of the N-terminal tail are the focus of intense study for their potential roles in opening or closing access to regions of DNA for expression. For example, acetylation of histone lysine residues (catalyzed by histone acetyltransferases) is associated with transcriptional activation. Conversely, histone deacetylation (catalyzed by histone deacetylase) leads to gene silencing. Histone deacetylases are recruited to areas of DNA methylation by DMT and by methyl–DNA-binding proteins, thus linking DNA methylation to histone deacetylation. Drugs inhibiting these enzymes have been demonstrated to be active anticancer agents and continue to be the focus of ongoing studies. The regulation of histone acetylation and deacetylation appears to be linked to gene expression, but the roles of histone phosphorylation and methylation are less well understood. Current research suggests that in addition to gene regulation, histone modifications contribute to the "epigenetic code" and are thus a means by which information regarding chromatin structure is passed to daughter cells after DNA replication occurs.

Regulatory Sequence Motifs in or Near Genes: Enhancers, Promoters, and Silencers

Several types of *cis*-active DNA sequence elements have been defined according to the presumed consequences of their interaction with nuclear proteins (see Fig. 1.5). *Promoters* are found just upstream (to the 5′ side) of the start of mRNA transcription (the CAP). mRNA polymerases appear to bind first to the promoter region and thereby gain access to the structural gene sequences downstream. Promoters thus serve a dual function of being binding sites for mRNA polymerase and marking for the polymerase the downstream point at which transcription should start.

Enhancers are more complicated DNA sequence elements. Enhancers can lie on either side of a gene or even within the gene. Enhancers are bound by enhancer binding proteins, thereby stimulating expression of genes nearby. The domain of influence of enhancers (i.e., the number of genes to either side whose expression is stimulated) varies. Some enhancers influence only the adjacent gene; others seem to mark the boundaries of large multigene clusters (gene domains) whose coordinated expression is appropriate to a particular tissue type or a particular time. For example, the very high levels of globin gene expression in erythroid cells depend on the function of an enhancer that seems to activate the entire gene cluster and is thus called a *locus-activating region* (see Fig. 1.5). The nuclear factors interacting with enhancers are probably induced into synthesis or activation as part of the process of differentiation. Chromosomal rearrangements that place a gene that is usually tightly regulated under the control of a highly active enhancer can lead to overexpression of that gene. This commonly occurs in Burkitt lymphoma, for example, in which the MYC proto-oncogene is juxtaposed and dysregulated by an immunoglobulin enhancer.

Silencer sequences serve a function that is the obverse of enhancers. When bound by the appropriate nuclear proteins, silencer sequences cause repression of gene expression. Some evidence indicates that the same sequence elements can act as enhancers or silencers under different conditions, presumably by being bound by different sets of proteins having opposite effects on transcription. *Insulators* are sequence domains that mark the "boundaries" of multigene clusters, thereby preventing activation of one set of genes from "leaking" into nearby genes. The concerted actions of enhancers, silencers, and insulators delineate the specific DNA sequences to be transcribed or prevented from transcription within an opened region of chromatin.

One way that activation of transcription of a genomic DNA segment is accomplished is by a "looping" out phenomenon whereby some DNA binding proteins first bind to each end of a potentially expressed segment of open chromatin; those proteins then bind to one other, pulling the ends together and forming a looped-out segment of chromatin. Additional factors then bind to enhancers, silences, promotors, and enhancers, thereby demarcating those parts meant for transcription or silencing. Loops, in other words, may be a secondary structure that identifies areas primed for transcription (see Fig. 2.1).

Transcription Factors

Transcription factors are nuclear proteins that exhibit gene-specific DNA binding. Considerable information is now available about these nuclear proteins and their biochemical properties, but their physiologic behavior remains incompletely understood. Common structural features have become apparent. Most transcription factors have DNA-binding domains sharing homologous structural motifs (cytosine-rich regions called zinc fingers, leucine-rich regions called leucine zippers, and so on), but other regions appear to be unique. Some factors recognize specific DNA sequence motifs within promoters, enhancers, silencers, or insulators and bind directly to them, whereas others bind to these factors, forming complexes that promote or inhibit transcription. Many factors implicated in the regulation of growth, differentiation, and development (e.g., homeobox genes, proto-oncogenes, antioncogenes) appear to be DNA-binding proteins and may be involved in the steps needed for activation of a gene within chromatin. These factors are discussed in more detail in several other chapters (see Chapters 2, 4, and 6); when mutated, many are involved in the pathogenesis of blood dyscrasias, such as c-myc and c-myb.

Regulation at the Level of Pre-mRNA and mRNA Metabolism

In eukaryotic cells, mRNA is initially synthesized in the nucleus (see Figs. 1.3 and 1.4). Before the initial transcript becomes suitable for translation in the cytoplasm, mRNA processing and transport occur by a complex series of events including excision of the portions of the mRNA corresponding to the introns of the gene (mRNA splicing), modification of the 5′ and 3′ ends of the mRNA to render them more stable and translatable, and transport to the cytoplasm. Moreover, the amount of any particular mRNA moiety in both prokaryotic and eukaryotic cells is governed not only by the composite rate of mRNA synthesis (transcription, processing, and transport) but also by its degradation by cytoplasmic ribonucleases (RNA degradation). Many mRNA species of special importance in hematology (e.g., mRNAs for growth factors and their receptors, proto-oncogene mRNAs, acute phase reactants) are exquisitely regulated by control of their stability (half-life) in the cytoplasm.

Posttranscriptional mRNA metabolism is complex. Only a few relevant aspects are considered in this section. Chapter 4 provides more detail.

Pre-mRNA Splicing

The initial transcript of eukaryotic genes contains several subregions (see Fig. 1.4). Most striking is the tandem alignment of exons and introns. Precise excision of intron sequences and ligation of exons is critical for production of mature mRNA. This process is called mRNA splicing, and it occurs on complexes of small nuclear RNAs and proteins called snRNPs; the term *spliceosome* is also used to

describe the intranuclear organelle that mediates mRNA splicing reactions. The biochemical mechanism for splicing is complex. A consensus sequence, which includes the dinucleotide GU, is recognized as the donor site at the 5′ end of the intron (5′ end refers to the polarity of the mRNA strand coding for protein); a second consensus sequence ending in the dinucleotide AG is recognized as the acceptor site, which marks the distal end of the intron (see Figs. 1.4 and 1.5). The spliceosome recognizes the donor and acceptor and forms an intermediate lariat structure that provides for both excision of the intron and proper alignment of the cut ends of the two exons for ligation in precise register.

mRNA splicing has proven to be an important mechanism for greatly increasing the versatility and diversity of expression of a single gene. Several different mRNA and protein products can arise from a single gene by selective inclusion or exclusion of individual exons from the mature mRNA products. This phenomenon is called *alternative mRNA splicing*. It permits a single gene to code for multiple mRNA and protein products with related but distinct structures and functions. The mechanisms by which individual exons are selected or rejected are complex and highly context-specific, varying among different cell types, differentiation stages, and physiologic states. Chapter 4 provides additional details. For present purposes, it is sufficient to note that important physiologic changes in cells can be regulated by altering the patterns of mRNA splicing products arising from single genes.

Many inherited hematologic diseases arise from mutations that derange mRNA splicing. For example, some of the most common forms of the thalassemia syndromes and hemophilias (see Chapters 41 and 134) arise by mutations that alter normal splicing signals or create splicing signals where they normally do not exist (activation of cryptic splice sites). Conversely, mutations altering key protein factors that modulate alternative splicing pathways are known to contribute to the pathogenesis of bone marrow dyscrasias (see Chapters 59, 61, and 66).

Modification of the Ends of the mRNA Molecule

Most eukaryotic mRNA species are polyadenylated at their 3′ ends. Polyadenylation results in the addition of stretches of 100 to 150 "A" residues at the 3′ end. Such an addition is often called the *poly-A tail* and is of variable length. Polyadenylation facilitates rapid early cleavage of the unwanted 3′ sequences from the transcript and is also important for stability or transport of the mRNA out of the nucleus. Signals near the 3′ extremity of the mature mRNA mark positions at which polyadenylation occurs. The consensus signal is AUAAA (see Fig. 1.4). Mutations in the poly-A signal sequence have been shown to cause thalassemia (see Chapter 41).

At the 5′ end of the mRNA, a complex oligonucleotide having unusual phosphodiester bonds is added. This structure contains the nucleotide 7-methyl-guanosine and is called *CAP* (see Fig. 1.4). The 5′-CAP enhances both mRNA stability and the ability of the mRNA to interact with protein translation factors and ribosomes.

5′ and 3′ Untranslated Sequences Within mRNAs That Modulate Stability and Translatability

Most mature mRNAs contain sequence motifs at the 5′and 3′ ends of the molecule extending beyond the initiator and terminator codons that mark the beginning and the end of the sequences actually translated into proteins (see Figs. 1.4 and 1.5). These so-called 5′ and 3′ untranslated regions (5′ UTRs and 3′ UTRs) influence both mRNA stability and the efficiency with which mRNA species can be translated. For example, if the 3′ UTR of a very stable mRNA (e.g., globin mRNA) is swapped with the 3′ UTR of a highly unstable mRNA (e.g., the c-myc gene), the c-myc mRNA becomes more stable. Conversely, attachment of the 3′ UTR of c-myc to a globin molecule renders it unstable. Instability is often associated with repeated sequences rich in A and U in the 3′ UTR (see Fig. 1.4). The UTRs in mRNAs coding for proteins involved in iron metabolism mediate altered mRNA stability or translatability by binding iron-laden proteins and thus govern iron storage and turnover (see Chapter 36).

Transport of mRNA From Nucleus to Cytoplasm: mRNP Particles

An additional potential step for regulation or disruption of mRNA metabolism occurs during the transport from nucleus to cytoplasm. mRNA transport is an active, energy-consuming process (Chapter 4). Moreover, at least some mRNAs appear to enter the cytoplasm in the form of complexes bound to proteins (mRNPs). mRNPs may regulate stability of the mRNAs and their access to translational apparatus. Some evidence indicates that certain mRNPs are present in the cytoplasm but are not translated (masked message) until proper physiologic signals are received.

Regulation of mRNA Processing and Stability

As mentioned earlier, cells can regulate the relative amounts of different protein isoforms arising from a given gene by altering the relative amounts of an mRNA precursor that are spliced along one pathway or another (alternative mRNA splicing). Many striking examples of this type of regulation are known—for example, the ability of B lymphocytes to make both immunoglobulin M (IgM) and IgD at the same developmental stage, changes in the particular isoforms of cytoskeletal proteins produced during red blood cell differentiation, and a switch from one isoform of the *c-myb* protooncogene product to another during red blood cell differentiation. Abnormalities of mRNA splicing due to mutations at the splice sites can lead to defective protein synthesis, as can occur in β-globin pre-mRNA, leading to some forms of β-thalassemia. The effect of controlling the pathway of mRNA processing used in a cell is to include or exclude portions of the mRNA sequence. These portions encode peptide sequences that influence the ultimate physiologic behavior of the protein, or the RNA sequences that alter stability or translatability.

The importance of the control of mRNA stability for gene regulation is being increasingly appreciated. The steady-state level of any given mRNA species ultimately depends on the balance between the rate of its production (transcription and mRNA processing) and its destruction. One means by which stability is regulated is the inherent structure of the mRNA sequence, especially the 3′ and 5′ UTRs. As already noted, these sequences appear to affect mRNA secondary structure, recognition by nucleases, or both. Different mRNAs thus have inherently longer or shorter half-lives, almost regardless of the cell type in which they are expressed. Some mRNAs tend to be highly unstable. In response to appropriate physiologic needs, they can thus be produced quickly and removed from the cell quickly when a need for them no longer exists. In contrast, globin mRNA is inherently quite stable, with a half-life measured in the range of 15 to 50 hours. This is appropriate for the need of reticulocytes to continue to synthesize globin for 24 to 48 hours after the ability to synthesize new mRNA has been lost by the terminally mature erythroblasts.

The stability of mRNA can also be altered in response to changes in the intracellular milieu. This phenomenon usually involves nucleases capable of destroying one or more broad classes of mRNA defined on the basis of their 3′ or 5′ UTR sequences. Thus, for example, histone mRNAs are destabilized after the S-phase of the cell cycle is complete. Presumably this occurs because histone synthesis is no longer needed. Induction of cell activation, mitogenesis, or terminal differentiation events often results in the induction of nucleases that destabilize specific subsets of mRNAs. Selective stabilization of mRNAs probably also occurs; for example, α-globin mRNA is stabilized by the protective binding of a specific stabilizing protein to a nuclease target sequence in its 3′ UTR.

Another critical mechanism that ensures the efficiency and fidelity of gene expression is nonsense-mediated decay (NMD). NMD has evolved to deal with the fact that common classes of mutations (either germ line or somatic, and including point mutations, “frame shifts” due to small deletions or insertions, and mutations causing mis-splicing; see Chapters 3 and 4) result in the creation of a premature translation termination codon in the translation reading frame (also stop codons or nonsense mutations). Nonsense codons can also be created by transcription or processing errors occurring during expression of normal genes. Indeed, as many as 5% to 30% of mature mRNA transcripts may carry nonsense codons in some cells under certain conditions. These mRNAs can be translated only into fragments of the intended protein and are thus physiologically useless. This impairs the efficiency of gene expression, expending the considerable energy required for even partial translation while serving no functional purpose. Moreover, those fragments fold abnormally and can trigger stress responses such as the unfolded protein response (Chapter 4) that can trigger other undesired cellular reactions. These fragments can also contain some of the functional domains of the intended complete protein. These can interact deleteriously with other cellular components, deranging cellular homeostasis.

NMD addresses these issues by recognizing nonsense codons and destroying the affected mRNA, thus avoiding its translation. The process exists across evolution from yeast to mammals. It is mediated by complex protein and RNA components functioning and supporting at least two recognition and destruction pathways. It is becoming clear that the integrity of these pathways is likely relevant to multiple disease states, including neoplasia.

Regulation at the Level of mRNA Translation

The amount of a given protein accumulating in a cell depends not only on the amount of the mRNA present but also on the rate at which it is translated into the protein and the stability of the protein. Translational efficiency depends in part on the structural features of any given mRNA, including polyadenylation, secondary structure of the 5′ and 3′ UTRs, and presence of the 5′ cap. The amounts and state of activation of protein factors needed for translation are also crucial. The secondary structure of the mRNA, particularly in the 5′ UTR, greatly influences the intrinsic translatability of an mRNA molecule by constraining the access of translation factors and ribosomes to the translation initiation signal in the mRNA. Secondary structures along the coding sequence of the mRNA may also have some impact on the rate of elongation of the peptide.

Changes in capping, polyadenylation, and translation factor efficiency affect the overall rate of protein synthesis within each cell. These effects tend to be global rather than specific to a particular gene product. However, these effects influence the relative amounts of different proteins made. mRNAs whose structures inherently lend themselves to more efficient translation tend to compete better for rate-limiting components of the translational apparatus, but mRNAs that are inherently less translatable tend to be translated less efficiently in the face of limited access to other translational components. For example, the translation factor eIF-4 tends to be produced in higher amounts when cells encounter transforming or mitogenic events. This causes an increase in overall rates of protein synthesis but also leads to a selective increase in the synthesis of some proteins that were underproduced before mitogenesis because they competed less well when the supply of active eIF-4 was limiting. It is also now being increasingly recognized that several classes of low-molecular-weight RNAs (micro-RNAs [miRNAs]) can have profound effects on the output of proteins from individual mRNAs or related groups of mRNAs by recognizing specific sequences in them and thereby altering stability or translatability.

Translational regulation of individual mRNA species is critical for some events important to blood cell homeostasis. For example, as discussed in Chapter 36, the amount of iron entering a cell is an exquisite regulator of the rate of ferritin mRNA translation. An mRNA sequence called the *iron response element* is recognized by a specific mRNA-binding protein but only when the protein lacks iron. mRNA bound to the protein is translationally inactive. As iron accumulates in the cell, the protein becomes iron bound and loses its affinity for the mRNA, resulting in translation into apoferritin molecules that bind the iron.

Tubulin synthesis involves coordinated regulation of translation and mRNA stability. Tubulin regulates the stability of its own mRNA by a feedback loop. As tubulin concentrations rise in the cell, it interacts with its own mRNA through the intermediary of an mRNA-binding protein. This results in the formation of an mRNA-protein complex and nucleolytic cleavage of the mRNA. The mRNA is destroyed, and further tubulin production is halted.

Heterogeneity of rRNAs and tRNAs

The 18 S and 28 S rRNAs, the many ribosomal proteins needed to assemble a ribosome, and tRNAs are encoded by many genes and are actually quite heterogeneous. The heterogeneity also varies among cell types and under varied cellular states such as the nutritional stress found in cancer cells. These variations appear to create significant alterations in the translatability of specific mRNAs. These effects can be blunted or accentuated by the tendency of different ribosome classes to favor or disfavor certain patterns of codon use. Disease states have been associated with mutations in these proteins and RNAs (ribosomeopathies), and manipulation of this complexity for therapeutic purposes is under intense investigation.

These few examples of posttranscriptional regulation emphasize that cells tend to use every step in the complex pathway of gene expression as points at which exquisite control over the amounts of a particular protein or RNA species can be regulated. In other chapters, additional levels of regulation are described (e.g., regulation of the production, stability, activity, localization, and access to other cellular components of the proteins that are present in a cell [see Chapters 6 and 7]).

Roles of Small Interfering RNAs, Micro RNAs, Short Hairpin RNAs, and Long Noncoding RNAs in Regulating Gene Expression

Cells were once thought to possess only three basic classes of RNA molecules: mRNA, rRNAs (5 S, 18 S, and 28 S), and tRNA. Moreover, the physiologic capacity of these RNA species was thought to be only informational, their nucleic acid sequences serving as codons, anticodons, or binding sites for ribosomal proteins, splicing and translation factors, mRNA transport factors, etc. Two fundamental discoveries have profoundly changed our view of the biologic role of RNAs. First was the recognition that some RNA molecules have catalytic activity that sustain key steps in gene expression such as pre-mRNA splicing. In cells, these activities are often carried out within ribonucleic acid (RNP) complexes. The second was the discovery that cells contain a potpourri of small RNA species in both the nucleus and the cytoplasm. Collectively these RNA moieties provide another layer of complex posttranscriptional mechanisms modulating gene expression. Some of these small RNAs might modulate transcription and processing as well.

One such process is carried out *by small interfering RNAs (siRNAs)*: short, double-stranded fragments of RNA containing 21 to 23 bp (Fig. 1.6). The process is triggered by perfectly complementary double-stranded RNA, which is cleaved by Dicer, a member of the RNase III family, into siRNA fragments. These small fragments of double-stranded RNA are unwound by a helicase in the RNA-induced silencing complex (RISC). The antisense strand anneals to mRNA transcripts in a sequence-specific manner and in doing so brings the endonuclease activity within the RISC to the targeted transcript. An RNA-dependent RNA polymerase in the RISC may then create new siRNAs to processively degrade the mRNA, ultimately leading to complete degradation of the mRNA transcript and abrogation of protein expression.

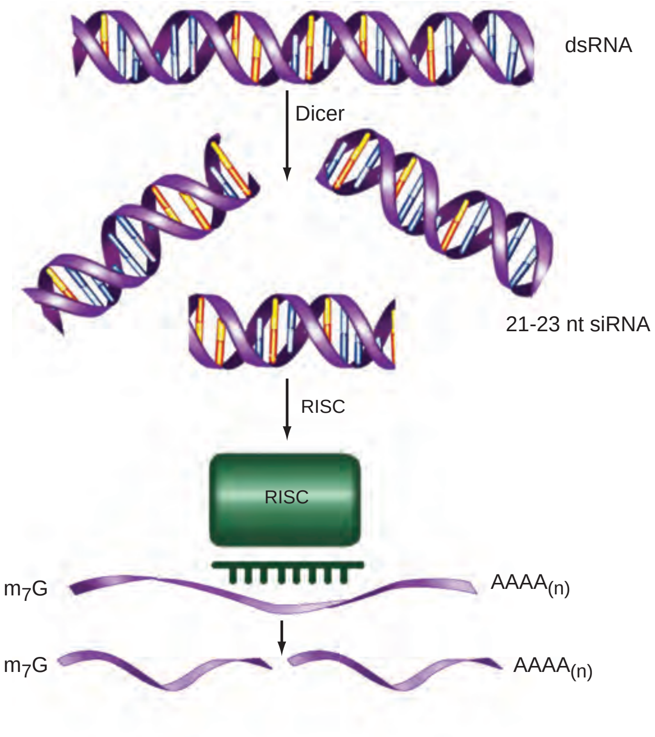

Figure 1.6 mRNA DEGRADATION BY siRNA. dsRNA is digested into 21- to 23-bp (base pair) small interfering RNAs by the Dicer RNase. These RNA fragments are unwound by RISC and bring the endonucleolytic activity of RISC to mRNA transcripts in a sequence-specific manner, leading to degradation of the mRNA. *dsRNA*, double-stranded RNA; *RISC*, RNA-induced silencing complex; *siRNA*, small interfering RNA.

Although this endogenous process likely evolved to destroy invading viral RNA, the use of siRNA has become a commonly used tool for evaluation of gene function. Sequence-specific synthetic siRNA may be directly introduced into cells or introduced via gene transfection methods and targeted to an mRNA of a gene of interest. The siRNA will lead to degradation of the mRNA transcript and accordingly prevent new protein translation. This technique is a relatively simple, efficient, and inexpensive means to investigate cellular phenotypes after directed elimination of expression of a single gene. Experimentally, engineered short hairpin RNAs (shRNAs) are used extensively to degrade or block the translation of a gene's mRNA product in a highly specific fashion, thus allowing one to target or "knock down" the expression of any gene or collection of genes at will and allowing assessment of a cell's behavior in the absence of expression of the targeted genes.

miRNAs, or MIRs, are 22-nucleotide small RNAs encoded by the cellular genome that alter mRNA stability and protein translation. These genes are transcribed by RNA polymerase II and capped and polyadenylated similar to other RNA polymerase II transcripts. The precursor transcript of approximately 70 nucleotides is cleaved into mature miRNAs by the enzymes Drosha and Dicer. One strand of the resulting duplex forms a complex with the RISC that together binds the target mRNA with imperfect complementarity. Through mechanisms that are still incompletely understood, miRNA suppresses gene expression, likely either through inhibition of protein translation or through destabilization of mRNA. miRNAs appear to have essential roles in development and differentiation and are aberrantly regulated in many types of cancer cells. The identification of miRNA sequences, their regulation, and their target genes are areas of intense study.

Other classes of small RNA molecules, such as circular or ringed RNAs and glycosylated RNAs, are under active study. Discussion of these is beyond the scope of this chapter. Moreover, a class of extraordinarily long RNA transcripts (long noncoding RNA [lncRNA]) has been known to exist for decades, but its functions are just beginning to be uncovered. lncRNA may be support an important mechanism for "opening" large domains of chromatin to access by mRNA polymerase (RNA polymerase II), transcription factors, enhancer- and silencer-binding proteins, etc., so the genes within that domain can be expressed. This might also provide clues into the role played by DNA "dark matter" in gene regulation, if the signals for the production, start points, and end points of lncRNAs are encoded in the regions "opened" by lncRNA transcription.

Some Illustrative Structural Features of the Genome Relevant to Hematology

Structural genes are separated from one another by as few as 1 to 5 kilobases or as many as several thousand kilobases of DNA. Almost nothing is known about the reason for the erratic clustering and spacing of genes along chromosomes. It is clear that intergenic DNA contains a variegated landscape of structural features that provide useful tools to localize genes, identify individual human beings as unique from every other human being (DNA fingerprinting), and diagnose human diseases by linkage. Only a brief introduction is provided here.

Polymorphism and Single Nucleotide Polymorphisms

The genomic landscape of each of our genomes is dotted with scattered sequence differences that distinguish us from any other living creature. These are a consequence of the nonzero error rate of base copying during normal DNA replication; under normal circumstances it is approximately $1/10^6$. In other words, one of 1 million bases of DNA will be miscopied (mutated) during each round of DNA replication. A set of enzymes called *DNA proofreading enzymes* corrects most of these mutations so that the rate of mutation following a normal cell division is closer to $1/10^9$. When these enzymes are themselves altered by mutation, the rates of mutation (and therefore the odds of neoplastic transformation) increase considerably. If these mutations occur in bases critical to the structure or function of a protein or gene, altered function, disease, or a lethal condition can result. Most pathologic mutations tend not to be preserved throughout many generations because of their unfavorable phenotypes. Exceptions, such as the hemoglobinopathies, occur when the heterozygous state for these mutations confers selective advantage in the face of unusual environmental conditions, such as malaria epidemics. These "adaptive" mutations drive the dynamic change in the genome with time (evolution).

Because these copying errors occur randomly most will occur in either the vast stretches of intergenic DNA or the "silent" bases of gene DNA, such as the degenerate third bases of codons. They thus do not pathologically alter the function of the gene or its products. These clinically harmless mutations are called *DNA polymorphisms*. DNA polymorphisms can be regarded in exactly the same way as other types of polymorphisms that have been widely recognized for years (e.g., eye and hair color, blood groups). They are variations in the population that occur without apparent clinical impact. Each of us differs from other humans in the precise number and type of DNA polymorphisms that we possess. Most polymorphisms represent single-nucleotide changes and are called single-nucleotide polymorphisms (SNPs).

DNA polymorphisms breed true. In other words, if an individual's DNA contains a G 1200 bases upstream from the α-globin gene, instead of the C most commonly found in the population, that G will be transmitted to that individual's offspring. Note that if one had a means for distinguishing the G at that position from a C, one would have a linked marker for that individual's α-globin gene. Before the completion of the human genome project, only limited regions of the genome could be analyzed by direct DNA sequencing and SNPs were detectable only if they altered the recognition site for one or more restriction endonucleases, enzymes that cut DNA only at sites possessing a specific recognition sequence (Fig. 1.7). SNPs not altering such sites were not readily detectable. Contemporary DNA sequencing methods now allow for routine comprehensive cataloging of SNPs in a population or individual. However, the principles of choosing the right comparison populations and of the "breeding true" through generations remain important principles in interpreting the results.

The importance of polymorphic variations in each is that they can be used to identify individuals uniquely and to compare two individuals at the genomic level. For example, the severity of sickle cell anemia varies greatly, even within families, even though the disease is always caused by a specific point mutation in the β-globin gene. This suggests that the products of other genes exert a modifying effect on clinical phenotype. By scanning the genomes of many sickle cell patients of varying severity, an SNP was identified in less severely affected individuals near the Bcl11a gene, which was then shown to participate in the perinatal shutdown of fetal hemoglobin synthesis. Less severely affected individuals turned out to express a less active variant of Bcl11a. Similarly, the pattern of variations in the polymorphisms strung along the HLA gene cluster on chromosome 6 (i.e., the "haplotype") can be measured to compare the HLA "match" between two individuals and assess the compatibility of a potential bone marrow donor and recipient. The term haploidentical transplant is derived form a donor-recipient pair who have matching HLA cluster haplotypes.

Repeated Sequence Motifs

A related important feature of the DNA landscape is the existence of highly repeated DNA sequence motifs. A DNA sequence is said to be repeated if it or a sequence very similar (homologous) to it occurs more than once in a genome. Some multicopy genes, such as the histone genes and the rRNA genes, are repeated DNA sequences. However, most repeated DNA occurs outside genes, or within introns. Indeed, 30% to 45% of the human genome appears to consist of repeated DNA sequences.

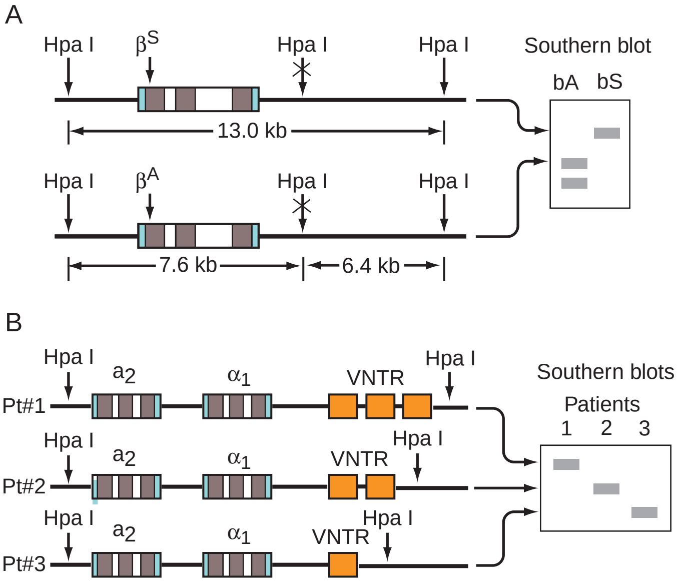

Figure 1.7 TWO USEFUL FORMS OF SEQUENCE VARIATION AMONG THE GENOMES OF NORMAL INDIVIDUALS. (A) Presence of a DNA sequence polymorphism that falls within a restriction endonuclease site, thus altering the pattern of restriction endonuclease digests obtained from this region of DNA on Southern blot analysis. (Readers not familiar with Southern blot analysis should return to examine this figure after reading later sections of this chapter.) (B) A variable-number tandem repeat (VNTR) region (defined and discussed in the text). Note that individuals can vary from one to another in many ways according to how many repeated units of the VNTR are located on their genomes, but restriction fragment length polymorphism differences are in effect all-or-none differences, allowing for only two variables (restriction site presence or absence).

The function of repeated sequences remains unknown, but their presence has inspired useful strategies for detecting and characterizing individual genomes. For example, a pattern of short repeated DNA sequences, characterized by the presence of flanking sites recognized by the restriction endonuclease Alu-1 (called "Alu repeats") occurs approximately 300,000 times in a human genome. These sequences are not present in the mouse genome. If one wishes to infect mouse cells with human DNA and then identify the human DNA sequences in the infected mouse cells, one simply probes for the presence of Alu repeats. The Alu repeat thus serves as a signature of human DNA.

Classes of highly repeated DNA sequences (tandem repeats) have proven to be useful for distinguishing genomes of each human individual. These short DNA sequences, usually less than a few hundred bases long, tend to occur in clusters, with the number of repeats varying among individuals (see Fig. 1.6). Alleles of a given gene can therefore be associated with a variable number of tandem repeats (VNTRs) in different individuals or populations. For example, there is a VNTR near the insulin gene. In some individuals or populations, it is present in only a few tandem copies, but in others, it is present in many more. When the population as a whole is examined, there is a wide degree of variability from individual to individual as to the number of these repeats residing near the insulin gene. It can readily be imagined that if probes were available to detect a dozen or so distinct VNTR regions, each human individual would differ from virtually all others with respect to the aggregate pattern of these VNTRs. Indeed, it can be shown mathematically that the probability of any two human beings sharing exactly the same pattern of VNTRs is exceedingly small if approximately 10 to 12 different VNTR elements are mapped for each person. A technique called *DNA fingerprinting* that is based on VNTR analysis has become widely publicized because of its forensic applications.

There are many other classes of repeated sequences in human DNA. For example, human DNA has been invaded many times in its history by retroviruses. Retroviruses tend to integrate into human DNA and then "jump out" of the genome when they are reactivated, to complete their life cycle. The proviral genomes often carry with them nearby bits of the genomic DNA in which they sat. If the retrovirus infects the DNA of another individual at another site, it will insert this genomic bit. Through many cycles of infection, the virus will act as a transposon, scattering its attached sequence throughout the genome. These types of sequences are called *long interspersed elements*. They represent footprints of ancient viral infections.

MOLECULAR GENETIC METHODOLOGIES ALLOWING THE ISOLATION, ANALYSIS, AND MANIPULATION OF GENES

The application of molecular genetics to the understanding, diagnosis, treatment, and prevention of hematologic diseases became possible in limited ways during the 1970s and 1980s, when a variety of experimental methods, both biochemical and genetic, made it possible to isolate any desired DNA fragment from chromosomes, or from DNA copies of cellular RNA (cDNAs). These methodologies, such as "Southern" blotting analysis of DNA, "Northern" blotting of RNA, and initial DNA sequencing techniques, although elegant, were laborious and required sophisticated personnel and equipment. They are now largely of historical interest, although still useful for some purposes. Four methodologies that made widespread routine use of DNA- and RNA-based disease-oriented research, diagnostics, and therapeutics feasible are the polymerase chain reaction (PCR), gene cloning, high-throughput DNA sequencing, and gene transfer techniques. The latter allows one to insert of the genetic material of choice into almost any desired cells, tissues, or organisms. All of these capabilities have been greatly enhanced by advances in computational methods, computerization, and automation. These four merit a brief introductory discussion because they are alluded to in many chapters in this book.

The Polymerase Chain Reaction

The development of the PCR revolutionized DNA-based strategies for diagnosis and treatment. It permits the detection, synthesis, and isolation of specific genes and allows one to discriminate among the alleles of a gene differing by as little as one base. It requires only readily available equipment and basic technical skills. A specimen consisting of only minute amounts of material will suffice; in most circumstances, no special preparation of the tissue is necessary. PCR made direct genetic and genomic analyses readily accessible to clinical, epidemiologic, and forensic laboratories. This single advance fueled quantum increases in the use of direct gene analysis for diagnosis of human diseases. Indeed, PCR analysis combined with direct DNA sequencing technologies have largely supplanted older strategies, such as restriction enzyme mapping and DNA/RNA blotting strategies for many research and diagnostic applications, although these older methods remain useful for some niche applications. PCR coupled with now-routinely available gene cloning methodologies allows one to synthesize in microgram quantities naturally occurring or engineered genes at will. These can then readily be inserted into cells, tissues, or organisms where they will be expressed and their physiologic or pathologic effects investigated. Similarly, industrial scale production of novel therapeutics based on the PCR-designed DNA itself or its expressed RNA or protein products is now routine. Hematopoietic growth factors and monoclonal antibody therapeutics are just two examples of widely used hematologic therapies that depended on these strategies.

PCR is based on the prerequisites for copying an existing DNA strand by DNA polymerase: an existing denatured strand of DNA to be used as the template and primers. Primers are short oligonucleotides, 12 to 100 bases in length, having a base sequence complementary to the desired region of the existing DNA strand. Oligonucleotide primers are now easily designed and produced using biochemical techniques developed in the 1970s and 1980s. The primer allows the polymerase to "know" where to begin copying. If the base sequence of the DNA of the gene under study is known (see DNA sequencing), two synthetic oligonucleotides complementary to sequences flanking the region of interest can be prepared. If these are the only oligonucleotides present in the reaction mixture, then the DNA polymerase can copy only daughter strands of DNA downstream from those oligonucleotides. In other words, it can copy only that gene. Recall that DNA is double stranded, that the strands are held together by the rules of Watson-Crick base pairing, and that they are aligned in antiparallel fashion. This implies that the effect of incorporation of both oligonucleotides into the reaction mix will be to synthesize two daughter strands of DNA, one originating upstream of the gene and the other originating downstream. The net effect is synthesis of only the DNA between the two primers, thus doubling only the DNA containing the region of interest. If the DNA is now heat denatured and then cooled again, allowing hybridization of the daughter strands to the primers, and the polymerization is repeated, then the region of DNA through the gene of interest is doubled again. Thus two cycles of denaturation, annealing, and elongation result in a selective quadrupling of the gene of interest. The cycle can be repeated 30 to 50 times, resulting in a selective and geometric amplification of the sequence of interest to the order of 2^{30} to 2^{50} times. The result is a millionfold or higher selective amplification of the gene of interest, yielding microgram quantities of that DNA sequence.

PCR achieved practical utility when DNA polymerases from thermophilic bacteria were discovered; when synthetic oligonucleotides of any desired sequence could be produced efficiently, reproducibly, and cheaply by automated instrumentation; and when DNA thermocycling machines were developed. Thermophilic bacteria live in hot springs and other exceedingly warm environments, and their DNA polymerases can tolerate 100°C (212°F) incubations without substantial loss of activity. The advantage of these thermostable polymerases is that they retain activity in a reaction mix that is repeatedly heated to the high temperature needed to denature the DNA strands into the single-stranded form. Microprocessor-driven DNA thermocycler machines can be programmed to increase temperatures to 95°C to 100°C (203°F to 212°F) (denaturation), to cool the mix to 50°C (122°F) rapidly (a temperature that favors oligonucleotide annealing), and then to raise the temperature to 70°C to 75°C (158°F to 167°F) (the temperature for optimal activity of the thermophilic DNA polymerases). In a reaction containing the test specimen, the thermophilic polymerase, a sufficient supply of primers to support the amplification, and the chemical components needed to sustain the multiple rounds of copying (e.g., nucleotide triphosphate precursors, reaction buffer, an adenosine triphosphate [ATP]-generating system to support the endothermic polymerase reaction), the thermocycler can conduct many cycles of denaturation, annealing, and polymerization in a completely automated fashion. The gene of interest can thus be amplified more than a millionfold in a matter of a few hours. The DNA product is readily identified and isolated by routine agarose gel electrophoresis. The DNA can then be analyzed by restriction endonuclease, digestion, hybridization to specific probes, sequencing, further amplification by cloning, and so forth.

Reverse transcriptases (RNA-dependent DNA polymerases) derived from retroviruses greatly extend the utility of PCR. By copying all the RNAs into their cDNAs, reverse transcriptase allows RNA sequences in a specimen to be amplified much like DNA sequences. This procedure, called reverse transcription (RT)-PCR, inserts a reverse transcriptase step into the beginning of the procedure, which then proceeds exactly like PCR. RT-PCR permits one to amplify all of the mRNAs expressed in a cell for high-throughput nucleotide sequence analysis, to detect just one or a few mRNAs to analyze their expression patterns, or to clone them (see later) to isolate their encoding genes.

High-Throughput DNA and RNA Sequencing

Knowing the nucleotide base sequence of a gene, its RNA products, its flanking regulatory elements, and its variation in a disease state is essential to understanding its normal or pathologic behavior. Techniques for sequencing (i.e., deciphering the nucleotide base sequence) DNA that emerged in the 1970s were valuable but limited. Only short stretches of a few hundred bases could be read during a single “run.” The methods required the use of radioactive tracers, sophisticated electrophoretic steps, and/or toxic chemicals. Nonetheless, the coding sequences of many genes relevant to hematologic disorders were obtained in this way. Fortunately, the human genome project inspired major technologic innovations (e.g., in the application of physicochemical and chromatographic principles to nucleic acid chemistry, the development of novel nonradioactive tracers, and the creation of software and firmware that allowed one to assemble the sequences of multiple independent sequencing “runs” of shorter fragments into a coherent sequence of the whole length of a gene). Sequencing of millions of nucleotides in a single sitting became feasible.

Modern sequencing techniques are commonly described as high-throughput sequencing or “next-gen” (i.e., next-generation) sequencing. Their efficiency and cost-effectiveness are such that whole genome sequences can now be gotten from a clinical specimen within a few days for a direct cost of less than a thousand dollars. The profound effect that these advances have had on the practical utility of DNA analysis in medicine is evident in the routine application of high-throughput sequencing to tumor specimens to identify therapeutic targets or infer prognostic information or the many thousands of SARS-CoV-2 genomes sequenced every day to track variants.

Next-gen sequencing has inspired the discipline of genomics, which attempts to understand the anatomy and functioning of any gene in the context of all of the DNA in the entire genome of a cell. Indeed, the technology has advanced to the point that one can sequence the genome of a single cell. Similarly, one can obtain the sequences of all of the mRNAs expressed in a specimen or even a single cell (the transcriptome) by first copying the cellular RNA into cDNA. This is called RNA sequencing or RNAseq.

Chapter 3 discusses genomics and the uses of sequencing technologies in hematology in greater detail.

Gene Cloning

PCR allows one to generate microgram amounts of pure DNA fragments up to a few kilobases in length. Most genes are considerably longer than that. To study their function or pathology, one needs to isolate the entire gene and its flanking sequences and insert it into cells for expression. Moreover, for any applications, such as manufacturing DNA reagents for diagnostic kits, the capability to generate much larger amounts is desirable. Gene cloning, or recombinant DNA technology, is a collection of methods that meets these goals. Basically, an amplified PCR fragment, or a mixture of all of the DNA fragments from a cell up to megabase lengths (1 megabase =1 million bp) generated by sonication or limited nuclease digestion, is modified at the ends with oligonucleotide “adaptors” that allow them to be ligated into a “vector.” In this context, a vector is an engineered microbial DNA element that can be inserted into a host cell, where it will coexist with the host genome and be able to be expressed. The most common vectors are viral genomes that were engineered to retain infectiousness but have had their pathogenic properties removed from their genomes.

If the “recombinant” genome has been placed in a bacteriophage genome and exposed to an excess of host bacterial cells, each cell acquires a single recombinant molecule. When cultured at low density on petri plates, each colony that grows out is a clone derived from a single transfected bacterium that in turn contains and expresses a single recombinant molecule. Many screening techniques have been devised by which one can identify and purify the clone(s) containing the desired DNA fragment among the thousands of clones on the plates. The clone can then be grown in bulk culture to generate large amounts of that DNA fragment for analysis, used as a diagnostic or experimental probe, or refined for use as a therapeutic, for transfer into cells, tissue, or whole organisms for studies of its biologic function. “Gene cloning” is thus named for the fact that the method allows one to capture, purify, and mass produce any single desired DNA fragment (e.g., a whole gene) in a single bacterial clone. This clone can also be preserved in a manner that sustains viability and be used repeatedly to generate additional DNA. Much of our contemporary molecular understanding of hematologic pathobiology has been gleaned by application of gene cloning approaches. Important therapeutics, such as erythropoietin, granulocyte-macrophage colony-stimulating factor (GM-CSF), monoclonal antibody therapeutics, CAR-T cells, and many more, are derived from recombinant DNA molecule purified by gene cloning methods.

Extensions and variations of techniques of gene cloning into bacteria have made possible the cloning of genes into cells of a wide variety of species, including human tissue culture cells. This adds great versatility to the methodology for expressing large quantities of the RNAs or proteins encoded by the cloned genes with all the appropriate posttranslation modifications present in their natural state.

Use of Transgenic and Knockout/Knockin Organisms to Model Gene Function

Recombinant DNA technology has resulted in the identification of many disease-related genes. To advance the understanding of the disease related to a previously unknown gene, the function of the protein encoded by that gene must be verified or identified, and the way changes in the gene’s expression influence the disease phenotype must be characterized. Analysis of the role of these genes and their encoded proteins was made possible by the development of recombinant DNA technology that allowed the production of mice that are genetically altered at the cloned locus. Mice can be produced that express an exogenous gene and thereby provide an in vivo model of its function. Linearized DNA is injected into a fertilized mouse oocyte pronucleus and reimplanted in a pseudopregnant mouse. The resultant transgenic mice can then be analyzed for the phenotype induced by the injected transgene. Placing the gene under the control of a strong promoter that stimulates expression of the exogenous gene in all tissues allows the assessment of the effect of widespread overexpression of the gene. Alternatively, placing the gene under the control of a regulatory sequence that can function only in certain tissues (a tissue-specific promoter) elucidates the function of that gene in a particular tissue or cell type. A third approach is to study control elements of the gene by testing their capacity to drive expression of a “marker” gene that can be detected by chemical, immunologic, or functional means. For example, the promoter region of a gene of interest can be joined to the cDNA encoding green jellyfish protein and activity of the gene assessed in various tissues of the resultant transgenic mouse by fluorescence microscopy. Use of such a reporter gene demonstrates the normal distribution and timing of expression of the gene from which the promoter elements are derived. Transgenic mice contain exogenous genes that insert randomly into the genome of the recipient. Expression can thus depend as much on the location of the insertion as it does on the properties of the injected DNA.

In contrast, any defined genetic locus can be specifically altered by targeted recombination between the locus and a plasmid carrying an altered version of that gene (Fig. 1.8). If a plasmid contains that altered gene with enough flanking DNA identical to that of the normal gene locus, homologous recombination can occur, and the altered gene in the plasmid will replace the gene in the recipient cell. Using a mutation that inactivates the gene allows the production of a null mutation, in which the function of that gene is completely lost. To induce such a mutation, the plasmid is introduced into an embryonic stem cell, and the rare cells that undergo homologous recombination

Figure 1.8 GENE "KNOCKOUT" BY HOMOLOGOUS RECOMBINATION. A plasmid containing genomic DNA homologous to the gene of interest is engineered to contain a selectable marker positioned so as to disrupt expression of the native gene. The DNA is introduced into embryonic stem cells, and cells resistant to the selectable marker are isolated and injected into a mouse blastocyst, which is then implanted into a mouse. Offspring mice that contain the knockout construct in their germ cells are then propagated, yielding mice with heterozygous or homozygous inactivation of the gene of interest.

are selected. The "knockout" embryonic stem cell is then introduced into the blastocyst of a developing embryo. The resultant animals are chimeric; only a fraction of the cells in the animal contain the targeted gene. If the new gene is introduced into some of the germline cells of the chimeric mouse, then some of the offspring of that mouse will carry the mutation as a gene in all of their cells. These heterozygous mice can be further bred to produce mice homozygous for the null allele.

Knockout mice reveal the function of the targeted gene by the phenotype induced by its absence. Methods for "knocking in" a gene have been developed to allow one to assess the functional consequences of replacing the function of the knocked-out gene with a modified version of that gene or an alternative gene with a related function. Genetically altered mice have been essential for discerning the biologic and pathologic roles of large numbers of genes implicated in the pathogenesis of human disease. These methods were originally developed in mice, but they have been extended to many animal species. The methods are now refined enough to generate recombinant organisms in which multiple endogenous genes are replaced by human genes, generating model organisms "humanized" for certain key functions (e.g., hemoglobin synthesis in mouse erythroid cells, certain immune functions); these humanized models are proving useful for preclinical testing of novel therapeutics.

DNA- AND RNA-BASED THERAPEUTICS

Gene Therapy and Gene Editing

The application of gene therapy to genetic hematologic disorders is an appealing idea. In some cases, this would involve isolating hematopoietic stem cells from patients with diseases with defined genetic lesions, inserting normal genes into those cells, and reintroducing the genetically engineered stem cells back into the patient. A few candidate diseases for such therapy include sickle cell disease, thalassemia, hemophilia, and adenosine deaminase–deficient severe combined immunodeficiency. The technology for separating hematopoietic stem cells and for performing gene transfer into those cells has advanced rapidly, and clinical trials are actively testing the applicability of these techniques. Indeed, the use of this "ex vivo" approach has led to the approval in Europe of a therapeutic gene for β-thalassemia. In other cases, such as treatments for hemophilia, the therapeutic gene is injected directly into a target tissue or infused. In both cases the gene must be packaged in a vector, usually a virus engineered to infect a particular cell type and to have lost any potential to cause a viral disease pathogenic. Presently, there are only few (but increasing, such as severe combined immunodeficiency syndromes, Wiskott–Aldrich disease, and thalassemia) proven therapeutic successes from gene therapy.

Progress in this field continues rapidly and is likely to accelerate as a consequence of the development of "gene editing" technologies (see Chapter 5). Among these, "CRISPR" is the most prominent current example. It is based on the discovery of enzyme systems used by microorganisms to excise foreign DNA sequences (e.g., integrated viral genomes) from the host genome. These systems can be adapted to insert, replace, or delete, in principle, any desired DNA sequence at its naturally occurring position in the host genome. For example, one could excise the mutation causing sickle cell anemia and replace it with the normal DNA sequence in the β-globin gene of a patient's hematopoietic stem cells and then reintroduce them into the patient's bone marrow without introducing any foreign DNA. This exciting technology is in clinical trials for a number of hematologic conditions, including hemoglobinopathies.

RNA Therapeutics

The recognition that abnormal expression of oncogenes plays a role in malignancy has stimulated attempts to suppress oncogene expression to reverse the neoplastic phenotype. One early attempt blocking mRNA expression is with antisense oligonucleotides. These are single-stranded DNA sequences 17 to 20 bases long, having a sequence complementary to the transcription or translation start of the mRNA. These relatively small molecules can be engineered with modified nucleotides that resist nucleotide destruction and freely enter the cell, where they complex to the targeted mRNA by Watson-Crick base pairing. Alternatively, one can use a modified gene therapy approach by transfecting the cells with a DNA segment encoding the antisense RNA. The binding of the oligonucleotide may directly block translation and clearly enhances the rate of mRNA degradation, thus downregulating the expression of the desired gene. The discovery, mentioned earlier, of naturally occurring small inhibitory RNAs has stimulated the development of RNA therapeutics that have largely superseded the original antisense approach.

RNA therapeutics is a burgeoning field of early drug development. Synthetic small hairpin RNAs containing modified nucleotides that stabilize them in the circulation and tissue spaces can be readily manufactured and engineered to contain any desired nucleotide sequences needed to identify and bind to only the targeted gene or RNA gene product, form metabolically active complexes with other intracellular

RNAs or proteins, and thereby achieve the desired therapeutic effect. RNA therapeutics are promising to be extremely versatile. In addition to binding to the target mRNA to block its translation and enhance its destruction, engineered shRNAs have been successfully designed to interact with the translational apparatus to "read through" or "skip over" nonsense codons, permitting completion of translation of the mutated protein, and to interact with the pre-mRNA splicing apparatus to alter the pattern of alternative mRNA splicing of the desired pre-mRNA in a physiologically favorable way. The latter strategy has been elegantly deployed to develop an FDA-approved therapy for spinal muscular atrophy. Using more conventional gene therapy methods to employ an shRNA targeting the binding of Bcl11a to its erythroid specific enhancer, thereby blocking the postnatal shutdown of fetal hemoglobin, is also being tested in clinical trials for treating sickle cell anemia and β-thalassemia.

FUTURE DIRECTIONS

The elegance of recombinant DNA technology and its successor technologies of genomics, epigenomics, proteomics, genetic therapies, gene editing, and RNA therapeutics resides in the capacity they confer on investigators to examine each gene as a discrete physical entity that can be purified, reduced to its basic building blocks for decoding of its primary structure, analyzed for its patterns of expression, and perturbed by alterations in sequence or molecular environment so that the effects of changes in each region of the gene can be assessed. Purified genes can be deliberately modified or mutated to create novel genes not available in nature. These provide the potential to generate useful new biologic entities, such as modified live virus or purified peptide vaccines, modified proteins customized for specific therapeutic purposes, and altered combinations of regulatory and structural genes that allow for the assumption of new functions by specific gene systems.

The most important impact of the genetic approach to the analysis of biologic phenomena is the most indirect. Diligent and repeated application of the methods outlined in this chapter to the study of many genes from diverse groups of organisms is beginning to reveal the basic strategies used by nature for the regulation of cell and tissue behavior. As our knowledge of these rules of regulation grows, our ability to understand, detect, and correct pathologic phenomena will increase substantially. So too will the complexity of ethical and policy issues about what comprises the appropriate and inappropriate uses of technologies capable of altering the nature of what it means to be human. For all of these reasons, it is incumbent on students of hematology to be as conversant with this discipline.

CHAPTER 2

EPIGENOMICS IN HEMATOLOGY

Myles Brown and Alok Tewari

Epigenetics can be defined as inheritance of variation, above and beyond changes in the DNA sequence. In other words, epigenetics comprises the study of how cells sharing the same exhaustive DNA blueprint can appear and function so distinctly as white blood cells, hepatocytes, neurons, etc. Whereas the genome contains all of the vital information to direct the development of an organism, the epigenome dynamically filters and organizes that information into highly coordinated programs of gene expression.

Within the nucleus, DNA interacts with histone and non-histone proteins to form chromatin, which can be broadly classified as highly compacted and transcriptionally silent (heterochromatin) versus loosely compacted and transcriptionally active (euchromatin). Heterochromatin comprises two distinct classes of DNA: (1) noncoding, often repetitive, "structural," DNA of centromeres and telomeres (constitutive heterochromatin), and (2) gene-encoding and gene-regulatory "functional," DNA that is selectively rendered inactive in different cell types (facultative heterochromatin). When euchromatin is described as loosely compacted, the information content of its DNA is readily accessible to binding the protein and RNA machinery that regulate gene expression. Therefore, the study of epigenetics and chromatin aims to describe and understand the chromatin dynamics that orchestrate the four-dimensional symphony of molecular and cellular biology, from the (seemingly) one-dimensional score that is the genome.

The information contained within chromatin can be grossly divided into two main categories: (1) the structural genes themselves, which are transcribed and translated into proteins or act as functional RNAs, and (2) gene-regulatory regions, which control the timing and amount of transcription (Fig. 2.1A). The information contained in transcribed and translated regions can be interpreted using the "genetic code," wherein the DNA sequence of the gene specifies, through a messenger RNA intermediate, the amino acid sequences of resulting proteins. While there is no universal genetic code to decipher the function of RNAs that are not translated into proteins, some such as ribosomal-RNA and transfer-RNA genes have well understood functions. In addition, several other classes of non-protein coding RNA genes with known functions exist, including small nuclear RNA (snRNA) involved in RNA splicing, Piwi-interacting RNA (piRNA) involved in silencing of transposable elements, small nucleolar RNA (sno-RNA) involved in directing the chemical modification of other RNA, and micro-RNA (miRNA) involved in translational silencing. A growing class of long noncoding RNA (lncRNA) have been identified, with a variety of proposed functions. Interestingly, these lncRNA genes appear to be regulated in much the same way as protein-coding genes. Protein-coding regions comprise approximately 1% to 2% of the genome. In contrast, the information contained in gene-regulatory regions is the "epigenetic code," which has yet to be fully deciphered and is based on the accessibility of those regions to dynamic protein-DNA interactions, the identity of those interacting proteins, and the identity of the gene(s) whose expression is being modulated.

The most dramatic example of chromatin compaction is the condensation that occurs during mitosis, making individual chromosomes visible by light microscopy and allowing segregation of replicates equally among daughter cells. A condensed or compacted chromosome is folded many times upon itself and is highly protein-bound, affording little or no access to genomic information and remaining transcriptionally silent (see Fig. 2.1B). Contrast this with the "decondensed," chromatin state that is necessary for DNA replication, during the synthesis phase of the cell cycle. DNA replication requires unfolding of chromatin, disruption of its protein-DNA interactions, and "unzipping," the double helix to allow every base in the genome to be copied. When not dividing, cells maintain their chromatin in intermediate states of compaction. Actively transcribed genes and their associated regulatory chromatin regions are "open," and "accessible," insofar as the underlying protein-DNA interactions are readily modified and disrupted to accommodate binding of transcription factors, cofactors, RNA polymerases, and the totality of functional components underlying gene expression.

It is important to remember some key differences between genomic and epigenomic research. Whereas the genome is essentially an unvarying feature of every cell in an organism (with the important exception of T and B cells that rearrange and mutate their antigen receptor genes), the epigenome of each cell within that organism is unique. Moreover, epigenomes are fluid throughout a cell's life span, integrating intrinsic cellular "identity," with contextual signals to specify a program of gene expression. Finally, the mechanics of DNA replication and cell division necessarily disrupt the protein-DNA interactions that comprise the epigenome. How cells re-establish their epigenetic identity, after cell division, is not well understood.

FUNCTIONAL CHROMATIN DOMAINS

Regulatory, noncoding DNA regions can have a variety of different functions, illustrated in Fig. 2.1A and variously classified as promoters, enhancers/silencers, super-enhancers, and insulators. Promoters are typically located within 1 to 2 kb of the transcriptional start site (TSS) of a gene. At a minimum, RNA-polymerase-II-dependent promoters contain binding sites for general transcription factors TBP and TFIIB, which form the core of the transcriptional complex. Within the promoter, transcription factor binding sites (TFBS) modulate gene expression by recruiting histone modifying enzymes and transcriptional coactivators or corepressors.

An enhancer/silencer is a short (50 to 1500 bp) region of DNA that can be bound by transcription factors to increase/decrease the likelihood that transcription of a particular gene will occur. Enhancers/silencers can act both in *cis* (within a chromosome) and rarely in *trans* (between chromosomes), can be located up to 1 Mb away from the gene, and can be upstream or downstream from the TSS. Promoters physically interact with their associated enhancers or silencers via three-dimensional chromatin "looping," facilitated by Mediator and Cohesin protein complexes (see Fig. 2.1D). Genes may be regulated by several enhancers/silencers, and each enhancer/silencer may modulate expression of one or more genes. A super-enhancer is a cluster of physically and functionally associated enhancers that regulates genes critical for cell identity. Super-enhancers are marked by high levels of enhancer-associated histone modification and bind high levels of cell-type specific and lineage-defining transcription factors (known as "master" transcription factors).

By blocking the physical interactions between enhancers and promoters, insulators help to restrict the set of genes that can be modulated by an enhancer. Insulators are bound by cohesin and CTCF proteins and form boundaries between silenced and active genes. Clusters of insulators separate heterochromatin from euchromatin, and the segments of active chromatin bounded by these clusters are known as topological domains-genomic regions, within which regulation occurs.

DNA METHYLATION

Methylation of cytosine by DNA methyltransferases (DNMTs) occurs at 60% to 90% of CpG dinucleotides, in the mammalian genome. Methylated DNA is bound by methyl-CpG-binding domain proteins (MBDs) that recruit histone-modifying enzymes and chromatin-remodeling proteins, resulting in highly condensed heterochromatin. Methylation of promoter regions thereby represses transcription. Patterns of DNA methylation are replicated during DNA synthesis, and cell division and can be used to distinguish cell types and stages of differentiation.

The genome-wide pattern of DNA methylation, known as the methylome, has been characterized for a wide variety of tissues. Approximately 75% of the methylome is consistent across all cell types. The remaining 25% is differentially hypo- or hypermethylated in a cell type-specific manner. Cell type-specific hypomethylated regions are enriched for nucleosomes with modifications associated with active regions and TFBSs, while cell type-specific hypermethylation is associated with transcription factor silencing during differentiation. Aberrant DNA methylation is an extremely common feature of cancers, where hypermethylation of tumor-suppressor genes and hypomethylation of oncogenes may play important roles in oncogenesis and tumor progression.

HISTONES AND HISTONE VARIANTS

Histones H2A, H2B, H3, and H4 are known as the core histones, while histones H1 and H5 are known as the linker histones. The core histones all exist as dimers, and the four dimers come together to form one octameric nucleosome core. The smallest unit of chromatin structure is the nucleosome, consisting of 147 base pairs of DNA double helix wrapped around the core histone octamer (see

Fig. 2.1C). Linker histones, primarily H1, bind the nucleosome at the entry and exit sites of the DNA and allow the formation of higher order structure. Histone N-terminal domains are rich in lysine and arginine residues that are subject to a variety of post-translational modifications (see below).

In addition to these major histones, dozens of minor histone variants have been identified and are highly evolutionarily conserved. Some minor variants have very specific roles in chromatin regulation. For example, histone H3-like CENPA is associated with centromeres. H2A.Z is associated with the promoters and enhancers of actively transcribed genes. Histone H3.3 is associated with the body of actively transcribed genes. Phosphorylated H2A.X is found in regions around double-stranded DNA breaks and recruits DNA-repair machinery.

COVALENT HISTONE MODIFICATIONS

Histones undergo a variety of post-translational modifications (including methylation, acetylation, phosphorylation, SUMOylation, citrullination, ubiquitination, and ADP-ribosylation) that alter their interactions with DNA and nuclear proteins (Fig. 2.2). Histone-modifying enzymes are broadly classified as "writers," such as histone methyltransferases (HMTs) and histone acetyltransferases (HATs) that add functional groups, or "erasers," such as histone demethylases (HDMs) and histone deacetylases (HDACs). DNA-binding proteins contain a variety of "reader," protein domains (including bromodomains, chromodomains, Tudor domains, SANT domains, etc.) that have increased affinity for modified histones. In this way, covalently-modified histones constitute a "histone code," that is a defining feature of the dynamic epigenome. Each of the eight histones in a nucleosome can harbor multiple covalent modifications, giving the histone code tremendous combinatorial complexity.

Trimethylation of H3 lysine 4 (H3K4me3) and of H3 lysine 36 (H3K36me3) are both associated with transcriptional activation. H3K4me3 occurs at the promoter of active genes, and the degree of trimethylation is broadly correlated with transcriptional activity of the gene. H3K36me3 is deposited by lysine methyltransferase KMT2A (also known as MLL1) component of the Mediator complex and occurs in the body of active genes. H3K36me3 associates with elongating RNA polymerase II, thus marking actively transcribed genes. Mono- and dimethylation of H3 lysine 4 (H3K4me1/2) and acetylation of H3 lysine 27 (H3K27ac) are marks of active enhancers, and the degree of H3K27ac is broadly correlated with enhancer activation. H3K27ac is the enhancer mark most used to define super-enhancers.

Several histone modifications are particularly associated with repressed genes: trimethylation of H3 lysine 27 (H3K27me3), di- and tri-methylation of H3 lysine 9 (H3K9me2/3), and trimethylation of H4 lysine 20 (H4K20me3). H3K27me3 is deposited at both promoters and enhancers by the PRC2 Polycomb complex and mediates recruitment of PRC1, resulting in chromatin condensation

Figure 2.2 HISTONE MODIFICATIONS AND HISTONE-MODIFYING ENZYMES. (A) The N-terminal tails of core histones contain lysine (K), arginine (R), serine (S), and threonine (T) residues that are common targets for a variety of post-translational modfications, including methylation (Me), acetylation (Ac), phosphorylation (P), and ubiquitination (Ub). (B) Histone-modifying enzymes can be broadly classified as either "writers" or "erasers" based upon addition or removal of functional groups, respectively. Moreover, many DNA-binding proteins contain "reader" protein domains (Bromodomains, SANT domains, Tudor domains, or Chromodomains) having increased affinity for acetylated, phosphorylated, methyl-arginine, and methyl-lysine modified nucleosomes, respectively. *HAT*, Histone acetyltransferase; *HDAC*, histone deacetylase; *KDM*, lysine demethylase; *KMT*, lysine methyltransferase; *PAD*, peptidylarginine deiminase; *PPTase*, protein phosphatase; *PRMT*, protein arginine methyltransferase.

and transcriptional repression. H3K9me2/3 and H4K20me3 are both highly associated with heterochromatin. H3K9me2/3 serves as a binding site for heterochromatin protein 1 (HP1). HP1 recruits additional histone-modifying enzymes, including the lysine methyltransferases, KMT5B and KMT5C, that produce H4K20me3.

Stem cells harbor promoters, marked by both activating H3K4me3 and repressive H3K27me3. Upon cellular differentiation, these "bivalent," or "poised," promoters are rapidly converted to either an activated or repressed state.

The Aurora B kinase phosphorylates histone H3 at serine 10 (phospho-H3S10), triggering the chromosome condensation during mitosis. Phosphorylation of H2B at serine 14 (phospho-H2BS14) mediates chromatin condensation during apoptosis.

TRANSCRIPTION FACTORS

Transcription factors are proteins that bind to specific DNA sequences, contribute to modulation of gene expression, and are the key determinants of the epigenetic state of the cell. Transcription factors are modular in structure and contain the following domains:

- DNA-binding domain (DBD), having high affinity for specific sequences of DNA,
- trans-activating domain (TAD) or trans-repressive domain (TRD), mediating protein-protein interactions with transcriptional coregulators, and
- an optional signal-sensing domain (SSD) (e.g., a ligand-binding domain), which can modulate DNA-binding and/or protein-binding activity, in response to cellular cues.

DNA sequences, having high affinity for transcription factor binding, are often referred to as response elements. Transcription factor binding to accessible promoters and enhancers recruits additional proteins, such as coactivators/corepressors, chromatin remodelers, histone-modifying enzymes, and RNA polymerases to modulate gene expression.

Although sequence-specific DNA binding is a defining feature of transcription factors, chromatin accessibility is a key determinant of transcription factor binding. Most transcription factors preferentially bind nucleosome-free DNA. In many cases, a transcription factor needs to compete for DNA binding with other transcription factors, histones, and non-histone chromatin proteins. The competitive balance between nucleosome and transcription factor binding is critically affected by chromatin remodeling complexes (see below). In practice, only a small fraction of potential response elements are actually bound, and many experimentally detected TFBS lack canonical response elements. The genome-wide pattern of transcription-factor binding can be experimentally determined using chromatin immunoprecipitation and next-generation sequencing (ChIP-seq, see below) and is known as the transcription-factor cistrome.

Different cell types typically express both common and distinct transcription factors. Moreover, the cistrome of a transcription factor differs among cell types, reflecting differences in chromatin accessibility and helping to define active promoters and enhancers. Master transcription factors are a special subset of lineage-defining transcription factors, having expression restricted to specific cell types and demonstrate very high binding at super-enhancers.

CHROMATIN REMODELERS

Chromatin remodeling alters the position, occupancy, or histone composition of a nucleosome within chromatin. ATP-dependent changes in nucleosome position and occupancy are mediated by the multisubunit, chromatin remodeling complexes, which fall into four families: SWI/SNF, ISWI, CHD, and INO80. ATP-independent changes in nucleosome position and occupancy can occur in response to transcription factor binding, or through the action of histone chaperones that can deposit, remove, or exchange histones. Each of these activities alters the accessibility of DNA to transcription factors and other DNA-binding proteins.

Complexes in the SWI/SNF family include the BAF, PBAF, and WINAC complexes they and contribute to transcriptional regulation and DNA repair. In addition to nucleosome sliding, SWI/SNF complexes have been implicated in chromatin looping, as well as eviction of H2A/H2B dimers from the nucleosome. Members of the INO80 family of complexes participate in transcription and DNA repair but can also catalyze the exchange of histones from the nucleosome structure. For example, SRCAP can exchange the H2A/H2B histone dimer for a variant H2A.Z/H2B dimer, which is associated with actively transcribed promoters. The CHD nucleosome remodeling family is the largest, and its best-characterized member is the NURD complex. A subset of NURD complexes incorporates the MBD2 subunit, which preferentially binds methylated DNA and promotes the repression of genes through its remodeling and HDAC activities. Many alternative NURD complexes incorporate different DNA-binding proteins and can contribute to transcriptional activation. ISWI family chromatin remodeling complexes catalyze the sliding of nucleosomes in short increments and participate in nucleosome spacing after DNA replication, RNA polymerase elongation, transcriptional regulation, and DNA damage repair.

Remarkably, cancer genome sequencing studies have identified frequent inactivating mutations in chromatin remodelers in a variety of human cancers. The SWI/SNF complex has particularly emerged as a powerful tumor suppressor whose disruption occurs in nearly 20% of primary human tumors.

EXPERIMENTAL APPROACHES IN EPIGENETICS

As dramatically as high-throughput sequencing has impacted our ability to understand the genome, its facilitation of epigenomic research has been equally profound. A wide variety of experimental approaches are in use and in development for epigenomic research, but most are predicated on detecting (1) DNA methylation, (2) protein-DNA interactions, (3) chromatin accessibility, and (4) three-dimensional chromatin structure/looping (Fig. 2.3).

A key feature of all these techniques is the ability to isolate a subset of DNA sequences from the larger genome, based upon a specific chromatin feature. This has several practical implications for experiments. First, many techniques rely on cross-linking agents, such as formaldehyde, to covalently link proteins to each other and to the DNA they bind. Cross-linking rapidly kills cells and "freezes" chromatin. Second, all these experimental techniques involve fragmenting chromosomes into much smaller pieces, either by physical disruption (sonication) or endonuclease treatment. Third, the chromatin subset of interest is extracted and enriched by immunoprecipitation, isolation of chromatin fragments of specific sizes, and/or sequence-specific amplification via polymerase chain reaction (PCR). Finally, DNA is isolated from this chromatin subset and subjected to next-generation sequencing.

A common technique for determining the genome-wide methylome is Bisulfite-seq. Treatment of DNA with bisulfite converts cytosine residues to uracil but leaves 5-methylcytosine (5mC) residues unaffected. Comparing results of bisulfite-treated and -untreated DNA sequencing permits genome-wide differentiation of methylated and un-methylated cytosines. Alternatively, methylated DNA immunoprecipitation (MeDIP-seq) utilizes an antibody, recognizing 5mC to enrich for methylated segments of the genome, prior to next-generation sequencing.

DNA binding by transcription factors, transcriptional machinery, structural proteins, and covalently modified histones can all be mapped in a genome-wide fashion using ChIP-seq. ChIP-seq typically requires cross-linking of proteins to DNA, using formaldehyde or other chemical fixation techniques. Antibodies are then used to enrich for a protein of interest, and the associated DNA fragments

identified by next-generation sequencing. ChIP-seq is the most versatile technique in epigenomic research. For example, genome-wide maps of histone modifications (such as H3K27ac or H3K36me3), active RNA polymerase II, insulator protein CTCF, superenhancer-associated Mediator complex, and transcription factors can all be accomplished via ChIP-seq, using different antibodies.

Assay for transposase-accessible chromatin (ATAC-seq) and DNase-seq are two techniques used to assess genome-wide chromatin accessibility. DNase-seq exposes native chromatin to cleavage by the DNase I endonuclease, the activity of which is inversely related to protein binding by DNA. Chromatin regions most sensitive to DNase I cleavage are termed DNase hypersensitive sites (DHSs) and are highly enriched for transcriptionally active and gene-regulatory segments of the genome. ATAC-seq is an alternative measure of chromatin accessibility, based upon susceptibility of chromatin regions to the activity of a hyperactive transposase. Transposase activity is highest in nucleosome-free regions, and ATAC-seq typically identifies transcriptionally active and gene-regulatory regions, largely similar to DNase-seq. Importantly, these two assays provide genome-wide snapshots of active chromatin regions, irrespective of the involved transcription factors or chromatin regulators.

Chromosome conformation capture (3C) techniques aim to identify three-dimensional chromatin loops, such as those bringing promoters near enhancers. All 3C-based methods begin with chromatin cross-linking. Following DNA fragmentation, a random DNA ligation step is performed to generate circular DNA molecules. Sequencing these DNA loops yields fragment pairs that, although separated by many kb in linearly organized DNA, are physically approximated in functional chromatin. 3C-based methods have tremendous potential to map enhancers to the genes whose activity they modulate. Beyond the original 3C method, which requires *a priori* selection of two potentially interacting genomic regions to allow for proper PCR primer design, several higher throughput techniques have been developed. These allow for the detection of interactions between a single genomic locus and other regions (4C), all genomic interactions within a given chromosomal region (5C), and all DNA-DNA interactions using high-throughput sequencing (Hi-C). Hi-C allows for the identification of topologically-associating domains (TADs), which are spans of the genome whose boundaries are marked by CTCF and cohesion binding; they associate more often with each other than other genomic regions. Disruption of TADs has been linked to multiple disease processes, including cancer.

Improved technical capabilities have led to the application of many of the above techniques to human tissue at both the bulk and single-cell level. For example, it is now feasible to profile both chromatin accessibility using ATAC-seq and transcription factor binding profiles using ChIP-seq in freshly acquired and frozen tissue. Though these assays are not currently feasible in formalin-fixed, paraffin-embedded (FFPE) tissue, it is possible to identify active enhancers in these samples, using ChIP-seq for acetylation at the histone H3K27 position. Single-cell analysis of chromatin accessibility, termed scATAC-seq, is also possible in fresh and frozen tissue. This approach allows for unprecedented analysis of cellular heterogeneity within tissues and can be combined with sequencing of transcribed RNAs from the same cells.

The fundamental challenge in epigenomic research is integrating the results of many different experiments to understand how the myriad chromatin features interact in regulating transcription and cellular behavior (Fig. 2.4). Thus, interpreting the epigenetic code requires measuring transcriptional activity in addition to chromatin features. Measurement of global transcript levels by mRNA sequencing (RNA-seq) is now the most common technique used to study gene expression, but interest is growing in the related genomic run-on sequencing (GRO-seq) and precision run-on sequencing (PRO-seq) techniques. These approaches measure active transcription, rather than total cellular transcript level and therefore holds promise for improved correlation with epigenomic data.

Several collaborative research consortia are dedicated to generating and curating genome-wide epigenetic data for public use, including the National Human Genome Research Institute's (NHGRI) ENCODE and Roadmap Epigenomics Projects. These resources include results of histone modifications and transcription factor ChIP-seq, DNase-seq, DNA Methyl-seq, and RNA-seq experiments for hundreds of human cancer cell lines and primary human tissues, respectively. The most versatile and widely available tool for visualizing epigenomic data is the UCSC Genome Browser, which incorporates easy access to ENCODE, Roadmap, and other data sources for integrative analysis of epigenomic and gene expression data (Fig. 2.5).

MECHANISMS OF DISEASE

The mechanisms of disease we describe here are not "strictly" epigenetic, insofar as they are all predicated on changes in genome sequence or structure (genetic mutations). Nonetheless, our insights into disease pathogenesis and development of novel therapeutic targets have been vastly informed by understanding the ways in which these genetic changes drive aberrant chromatin regulation and gene expression. The examples given below represent only a subset of the known epigenetic drivers of disease.

Sickle cell anemia has long been known to result from a point mutation in the hemoglobin beta gene. The severity of this often life-threatening hemoglobinopathy is attenuated in patients having increased expression of the fetal gamma hemoglobin variant, a trait known as hereditary persistence of fetal hemoglobin (HFPH). Genome-wide association studies in patients with HFPH identified frequent single nucleotide polymorphisms (SNPs) in a small number of noncoding regions, near the BCL11A gene on chromosome 2. Subsequent studies have elegantly demonstrated that these SNPs are in erythroid-specific enhancers, modulating BCL11A expression. The HFPH-associated SNPs diminish binding of transcription factors GATA1 and TAL1, which results in decreased expression of BCL11A. Because BCL11A is required for efficient silencing of fetal hemoglobin expression, sickle cell anemia patients having these common variant SNPs demonstrate elevated fetal hemoglobin throughout adulthood and are often protected from the most severe manifestations of the disease. Just as sickle cell anemia is among the most striking examples of disease, caused by a point mutation in the coding region of a gene, these BCL11A enhancer SNPs demonstrate the power of gene-regulatory elements to modulate the sickle cell disease phenotype.

Chromosomal translocations that result in aberrant expression of oncogenes or leukemogenic transcription factors are another common mechanism of disease. The classical example of this is Burkitt's lymphoma, in which t(8;13) translocations juxtapose the highly active immunoglobulin heavy chain enhancers and the c-myc oncogene, driving myc overexpression and oncogenic transformation of mature B cells. Similarly, many different translocations have been identified in T acute lymphoblastic leukemia (T-ALL), whereby overexpression

Integrating publicly-available, genome-wide data for a variety of epigenomic experiments is the cornerstone of efforts to decode the epigenome.

of master transcription factors such as TAL1, LMO1, LMO2, and HOX11 is driven by chromosomal rearrangements involving the T-cell receptor loci.

An alternate mechanism driving TAL1 overexpression in T-ALL has recently been described, in which small genomic insertions (2 to 18 bp) upstream of the TAL1-coding region introduce novel binding sites for the MYB transcription factor. This aberrant MYB binding recruits additional transcription factors RUNX1, GATA-3, and TAL1, as well as the HAT CBP and forms a super-enhancer driving leukemogenic TAL1 overexpression.

Many different translocations resulting in fusion of the mixed-lineage leukemia (MLL1/KMT2A) gene, located on chromosome 11q23, with over 70 different partner proteins have been identified in infant ALL and therapy-associate acute myeloid leukemia (AML). Only recently have the mechanisms underlying the leukemogenic nature of these translocations been elucidated. Leukemogenic MLL1 fusion proteins fuse the N-terminal targeting domain with a transcription elongation factor, such as ENL or AF9. The resulting fusion protein drives overexpression of common MLL1 targets by recruiting the DOT1L complex (having H3K79 methyltransferase activity) and the positive transcription elongation factor b (P-TEFb) complex (containing CDK9 and phosphorylating RNA PolII). Moreover, a subset of leukemogenic MLL1 fusions can inhibit the transcriptional repressive activity of PRC1. In summary, MLL translocations in ALL and AML define a paradigm of leukemia development, based upon transcriptional dysregulation through aberrant targeting and control of transcription elongation activity.

As noted earlier, inactivating mutations in components of chromatin remodeling complexes, such as SWI/SNF, have been identified in a wide variety of human cancers. For example, a recent study found mutations in the ARID1A subunit of SWI/SNF in 17% of Waldenström's macroglobulinemia cases, and patients with ARID1A mutations had more aggressive disease features. In addition to their nucleosome remodeling activities, chromatin remodeling complexes contribute to three-dimensional chromatin structure, participate in DNA damage repair, modulate transcription factor binding, and recruit histone-modifying enzymes. Precisely how disruption of these many chromatin regulatory activities contributes to disease is an extremely active area of research.

In addition to these epigenetic contributions to disease development, much interest has evolved in potential epigenetic mechanisms of resistance to existing cancer therapies. One example of this is resistance of T-ALL to γ-secretase inhibitors (GSIs), used to target abnormal NOTCH1 activation. In vitro, treatment of T-ALL cell lines with GSIs kills a large proportion of cells but leaves behind a "persister" population of GSI-resistant cells. If GSI treatment is removed, these persister cells revert to their prior GSI-sensitive state, suggesting an epigenetic mechanism of drug resistance. A screen of chromatin regulators, required for persister cell viability, identified the bromodomain containing 4 protein (BRD4), a key factor in activating transcriptional elongation. This study, and many others, has ignited broad interest in other potential epigenetic mechanisms of therapy resistance, as well as BRD4 as a specific therapeutic target.

EPIGENETIC THERAPIES

Epigenetic therapies are among the most active areas of pre-clinical and clinical cancer research, due to their potential to specifically target chromatin-mediated disease mechanisms and the expectation that these therapies will have fewer side effects than conventional cytotoxic chemotherapies. As seen in Table 2.1, several classes of drugs have emerged, and we will briefly discuss the rationales for their ongoing development.

The first class of epigenetic drugs to show significant clinical benefit is the DNMT inhibitors, particularly 5-azacytidine and its analog decitabine. As discussed earlier, abnormal DNA methylation is a common feature of many cancers. However, azacytidine is primarily beneficial in treating myelodysplastic syndromes (MDS) and AML. The theoretical basis for this therapeutic effect is re-activation of key tumor suppressor genes, by disruption of DNA methylation at their promoters. However, this mechanism has not yet been confirmed in azacytidine-treated patients, and alternate mechanisms of action are under investigation.

TABLE 2.1 Emerging Epigenetic Therapies

Class	Target	Disease
DNA methylation inhibitors	DNMTs	MDS, AML
Histone-modifying enzymes		
HMT inhibitors	DOT1L, EZH2, non-specific	MLL-rearranged leukemias, NHL, MDS, AML
HDAC inhibitors	HDAC6, non-specific	MM, CLL, lymphoma
HMT activators	SIRT1, SIRT5	MM
HDM inhibitors	KDM1A	AML
Bromodomain inhibitors	BRD4, p300/CBP, non-specific	Hematologic malignancies

AML, Acute myeloid leukemia; *BRD4*, bromodomain containing 4 protein; *CLL*, chronic lymphocytic leukemia; *DNMTs*, DNA methyltransferases; *HDAC*, histone deacetylase; *HDM*, histone demethylase; *HMT*, histone methyltransferase; *MDS*, myelodysplastic syndrome; *MM*, multiple myeloma; *NHL*, non-Hodgkin's lymphoma.

By far the largest class of epigenetic therapies is inhibitors of histone-modifying enzymes. Drugs inhibiting HMTs and HDACs are most prevalent, though several compounds that activate HDACs or inhibit HDMs are also being developed. For example, inhibitors of the H3K79 methyltransferase DOT1L are in clinical trials for MLL-rearranged leukemias. Alternately, inhibitors of the H3K27 methyltransferase EZH2 (the catalytic component of the PRC2 complex) are being tested in multiple hematologic malignancies. Specific inhibitors of HDAC6 are being used in trials for multiple myeloma, while drugs having broad HDAC-inhibitory activity are in ongoing trials for a wide variety of hematologic malignancies.

Newer classes of epigenetic therapies include bromodomain inhibitors that target the BET proteins and others such as p300. As discussed briefly above, bromodomains are an extremely common feature of DNA-binding proteins and preferentially recognize acetylated chromatin. The abundance of bromodomain-containing, DNA-binding proteins makes development of substrate-specific drugs extremely challenging. However, initial clinical trials using BET bromodomain inhibitors, having broad binding specificity, have been very promising in a wide variety of advanced hematologic and non-hematologic malignancies. The likely therapeutic targets of these drugs are the transcriptional machinery itself, though many additional mechanisms plausibly contribute.

FUTURE DIRECTIONS

Interpreting the "epigenetic code" holds great potential for bridging the gaps between the molecular biology of the genome, cellular biology, and physiology of health and disease. The application of next-generation sequencing technology and development of novel techniques to interrogate chromatin have produced a profusion of new epigenetic data. Collaborative epigenomics projects such as ENCODE and the Epigenome Roadmap, as well as genomics efforts such as the 1000 Genomes Project and the Cancer Genome Atlas, make these vast data widely available to researchers. The substantial challenge remains integrating and interpreting these data to generate novel insights into human health and disease. Substantial collaboration between biomedical scientists, computational biologists, and physicians will be necessary to design, execute, and analyze projects with high relevance to medical progress.

CHAPTER 3

GENOMIC APPROACHES TO HEMATOLOGY

Gareth J. Morgan and Eileen M. Boyle

INTRODUCTION

The publication of the sequence of the human genome in 2001[1] heralded a new era in biomedical research and delivered a novel perspective on the biologic basis of the leukemias and lymphomas. A major tenet of these new approaches was their emphasis on the generation of large unbiased datasets as a means of discovery. The rapid application of this methodology combined with ready access to tissue for analysis pushed hematology into an era of "*precision medicine*" based on the use of molecular diagnostics and targeted interventions. The speed with which this approach was taken up was enhanced by the reduction in sequencing costs, which made testing generally available. In the background, large-scale efforts led to the establishment of repositories of genomic data (e.g., The Cancer Genome Atlas[2]), which allowed the development of effective diagnostic, prognostic, and predictive biomarkers. The extension of this information by integrating molecular markers into the World Health Organization (WHO) classification enhanced disease definitions, making their behavior easier to understand and predict.[3] Risk-stratified therapy based on the integration of molecular markers is now a reality for many hematologic cancers, and the development of predictive markers is a particular aim based on targeting specific genomic variants (e.g., BRAF inhibitors targeting *BRAF* V600E mutations). This chapter describes the approaches and progress that have been made for the integration of genomic approaches into the clinic to improve the management of hematologic diseases.

GENERAL PRINCIPLES OF GENOMIC TESTING

Genomic Analysis

Analysis of the genome (Table 3.1) aims to identify, quantify, or compare genomic features such as DNA sequence, structural variation (SV), gene expression, or regulatory and functional annotation at a genomic scale. Methods for genomic analysis typically require high-throughput sequencing and computational analysis.

DNA-based whole genome high-throughput sequencing approaches for the detection of genetic variants have been used to identify differences between individuals or pathologic conditions. Typically, this approach aims at identifying single-nucleotide variants (SNVs), small insertions and deletions (indels), and SVs. SVs are diverse, ranging from approximately 50 base pairs (bp) to more than megabases in size, and affect more of the genome than any other class of sequence variant. They comprise a number of subclasses of unbalanced copy number abnormalities (CNAs), which include deletions, duplications, and insertions, as well as balanced rearrangements, such as inversions and interchromosomal and intrachromosomal translocations. In addition, SVs include mobile element insertions, multiallelic copy number variants of highly variable copy number, segmental duplications, and complex rearrangements that consist of multiple combinations of these events.

Genome-wide analysis of gene expression, also referred to as transcriptomics, is the study of transcription at the genomic scale. These analyses use RNA and analysis results from microarrays or high-throughput sequencing. The results can be used to determine the range of genes expressed and their isoforms within a particular cell or tissue type, for a disease, or associated with a clinical phenotype such as risk status.

The epigenome refers to the changes made to the DNA that govern its function and include methylation and acetylation of DNA, histones, nonhistone chromatin proteins, and nuclear RNA. The tools for studying epigenetic phenomena are focused on the global analysis of epigenetic status of the cells and tissues. With improvements in epigenomic profiling, new opportunities are available to understand normal epigenomes and their perturbations in cancer.

The Importance of Sample Quality

The acquisition of the appropriate samples for a genomic analysis is one of the most crucial steps for the generation of an accurate result. This is particularly true for gene expression analysis based on samples of RNA. Gene expression is a dynamic process that can be affected by cellular manipulation, RNA abundance and stability, isolation methodology, and the time between when the sample was obtained and subsequently isolated. The highest-quality RNA is obtained if, as soon as possible after harvesting a sample, cells are dissolved in a solution that inactivates RNase enzymes. It is also possible to measure gene expression from stored tissue such as formalin-fixed, paraffin-embedded (FFPE) tissues, but the variability in quality of these data makes routine interpretation difficult. The cellular makeup of samples for RNA analysis is also important (e.g., tumor cells, normal cells, stromal cells, and immune cells) if tumor-specific expression patterns are important; if this is the case, then methods for cell separation are required. This requirement may be less of an issue in tissues such as bone marrow samples taken from patients with acute myeloid leukemia (AML), where the number of blasts cells is high; however, if the percentage of blast cells is low, a selection approach is required. Methods used for this purpose include: flow cytometry, immunomagnetic bead sorting, and laser-capture microdissection. A good example of where cell selection is important is in multiple myeloma, where CD138 selection is crucial for gene expression analysis and is mandated in guidelines for interphase fluorescence in situ hybridization (iFISH) analysis.[4]

At the DNA level the admixture of nonmalignant cells within a tumor may obscure the presence of mutations in the tumor cells, especially if they constitute a minority population. However, to be sure of detecting mutations in a tumor cell population, a greater depth of sequencing is required. Therefore it is critical to have a rough estimate of the purity of the sample so that the appropriate genomic approach can be used. Furthermore, the clonal fraction of tumor cells carrying a specific mutation is important if it is considered to be "actionable." In this respect, knowing the subclonal percentage is important not only for detecting the mutation but also to be sure that a therapeutic benefit could be expected.

Analytical Considerations

It is important to distinguish approaches used for discovery from those required for a routine diagnosis. For discovery, unsupervised learning approaches are used in which samples are grouped on the basis of data obtained without regard to any prior knowledge of either the samples or the disease. Unsupervised learning methods that have been used include hierarchical clustering, principal component analysis, nonnegative matrix factorization, *k*-means clustering,

TABLE 3.1 **Definition of the Different Genomes**

Nuclear genome represents the DNA that may be found within the nucleus of a cell that encodes the majority of DNA in eukaryote cells. In humans, it comprises approximately 3,200,000,000 nucleotides, divided into 24 linear sections, each contained in a different chromosome. These 24 chromosomes consist of 22 autosomes and the two sex chromosomes. The vast majority of cells, somatic cells, are diploid (in contrast to gametes, which are haploid). The spontaneous mutation rate of nuclear DNA is low (0.3%).

Mitochondrial genome: is a closed circular DNA molecule of approximately 16,500 nucleotides, present within the mitochondria. It contains 37 genes, all of which are crucial for normal mitochondrial function. Thirteen of these genes encode enzymes involved in oxidative phosphorylation; the remaining genes code for transfer RNA (tRNA) and ribosomal RNA (rRNA). Haploid, the mitochondrial genome is inherited through the mother. It has a higher mutation rate than nuclear DNA, that is overcome by the multiple copies (100–10,000) present in one cell.

Epigenome: The epigenome comprises specific covalent modifications of the chromatin that ensure the somatic inheritance of differentiated cell states. Not only does it act during the differentiation of somatic cells but also in response to environmental cues and stresses. The passing on of these modulations to the descendants constitutes epigenetic inheritance. The structure and function of the epigenome are controlled by covalent marks applied to components of a nucleosome (DNA and histones) by enzymes (“writers”). These marks instruct the proteins that recognize them (“readers”) to identify and remodel particular regions of the genome in order to modulate expression. The plasticity of the epigenome comes from the “erasers”, enzymes capable of removing active and repressive marks. Disturbed in cancers, epigenetic changes modulate both the structure and the function of the chromatin.

Microbiome: is genetic material of all bacteria, fungi, protozoa, and viruses that live on and within the human body. Its role in disease susceptibility is largely unknown. Recent technologic advances in DNA sequencing and the development of metagenomics have made it feasible to analyze the entire human microbiome and to gain insight into its composition.

and *t*-distributed stochastic neighbor embedding. Great care must be taken in the interpretation of clustering results because clusters may be caused by irrelevant factors such as sample processing, termed batch effect. Adjustments and normalization processes may be required to account for batch effects to minimize the effect of sample processing and to ensure comparability. Unsupervised learning approaches have been used to cluster leukemia, lymphoma, or myeloma, based on their gene expression profiles, with the goal of uncovering the most robust classification schemes. In myeloma, this approach led to the description of the Translocation Cyclin D classification, which described the major molecular subtypes of disease.[5]

In contrast to unsupervised approaches, supervised learning approaches are best suited for comparing data between classes of samples that can be distinguished by a known property, such as biologic subtype or clinical outcome. For example, to determine the gene expression differences between different leukemia subtypes with distinct genetic abnormalities, one would use a supervised approach.

For routine diagnostic testing the optimum analysis approach is to have a clear idea of the information required and to report the data in a yes/no binary fashion to ensure clinical interpretability.

NEXT-GENERATION SEQUENCING TECHNOLOGY

Next-generation sequencing (NGS) has transformed the field of molecular diagnostics, leading to its routine uptake in clinical care. A single lane on a modern sequencer generates a huge amount of data, allowing for multiplexing and testing of samples.

RNA Profiling

In the late 1990s, profiling was done using an array format in which sequence-specific probes were immobilized onto a solid surface mRNA. These probes were hybridized to RNA from a sample of interest that was labeled with a fluorescent tag, and the array was captured by a laser-scanning device.[6] However, more recently sequencing-based approaches (RNA sequencing [RNA-seq]) have come to dominate because they allow for the profiling of previously unknown genes, alternative splice forms of known mRNAs, and gene fusions.[7]

Expression profiling of FFPE tissues deserves consideration because formalin fixation causes the degradation of mRNAs into fragments of only approximately 80 nucleotides in length. Array-based profiling approaches do not work well, particularly those that involve labeling of the mRNAs by priming of the 3′ polyadenylation tail. However, approaches have been developed that allow for the profiling of FFPE-derived tissues such that even degraded mRNAs can be profiled. Although it is likely that any method applied to FFPE samples will yield “noisier” data than frozen samples, the ability to analyze archived material, particularly those samples with long-term clinical outcome data, is sometimes invaluable. An example of this type of utility is the Lymphoma/Leukemia Molecular Profiling Project (LLMPP) Lymph2Cx assay, which is a parsimonious digital gene expression–based test (NanoString) for cell of origin (COO) assignment in FFPE tissue routinely produced from standard diagnostic processes.[8] The NanoString’s nCounter technology is a variation on the DNA microarray and uses molecular barcodes and microscopic imaging to detect and count-up to several hundred unique transcripts in one hybridization reaction.[9]

Noncoding RNA

Two major classes of noncoding RNAs are short RNAs, known as *microRNAs* (miRNAs), and *large intergenic noncoding RNAs* (lincRNAs). miRNAs are small (approximately 22-nucleotide) RNAs that do not encode for proteins but bind to mRNA transcripts to regulate translation and mRNA stability. Several hundred miRNAs are thought to exist in the human genome. In mammalian cells, a role for miRNAs has been recognized in the regulation of cellular differentiation through regulation of translation of key proteins. Not only are many miRNAs differentially expressed across hematopoietic lineages, but several miRNAs have also been demonstrated to play key functional roles in hematopoietic lineage specification and differentiation. The expression and/or function of several miRNAs is altered by chromosomal translocations, deletions, or mutations in leukemia and other hemopoietic disease. In addition, members of the protein complex, including the protein DICER, that process the maturation of miRNAs from longer RNA forms, have been implicated in malignancy.[10] Long noncoding (lnc)RNAs are approximately 1000 nucleotides in length and number approximately 5000 in the human genome. Recent evidence suggests that they may play important roles in establishing and maintaining cell fate and may play key roles in regulation of the epigenome. Interestingly, lncRNAs appear to have exquisite tissue-specific patterns of expression, suggesting that they may have diagnostic potential.

Mutation Detection Strategies

NGS can yield near-perfect fidelity for the detection of a mutation at a specific site, but at the same time, the error rates for any given sequencing read can be as high as 1%. This paradox reflects the fact that most sequencing errors are idiosyncratic, and, by simply resequencing the same region multiple times, developing a consensus results in such errors being lost. Thus, for normal, diploid genomes, sequencing is typically done to at least 30-fold coverage, meaning 30 reads for any given locus (referred to as *30× coverage*). The coverage is influenced by copy number changes (e.g., aneuploidy or regions or gene deletion or amplification) or when there is admixture of normal cells within the tumor sample. To compensate for these copy number variations and normal cell contamination, typical cancer sequencing projects aim for a depth of coverage of at least 100×.

The US Food and Drug Administration (FDA) has issued guidelines[11] for test design, performance characteristics, run quality metrics, performance evaluation, variant annotation, and filtering. The guidance identifies six key aspects of test design: the indications for use statement, user needs for the tests, specimen type, the region of the genome being interrogated, performance needs, and components and methods. The guidance further identifies four key aspects of test performance: accuracy, precision, limit of detection, and analytical specificity. They also specify six test run quality metrics: coverage, specimen quality, DNA quality and processing, sequence generation base calling, mapping or assembly metrics, and variant calling metrics. Several minimum standards for test performance and quality metrics are suggested, including the following:

- a point estimate of 99.9% accuracy (e.g., positive predictive agreement, negative predictive agreement, and technical positive predictive value) with a lower bound of the 95% confidence interval of 99.0% for all variant types reported;
- reproducibility and repeatability of at least 95% of the lower bound of the 95% confidence interval;
- a minimum coverage (i.e., depth and completeness threshold) of 20× for targeted panels and 30× average coverage depth at 100% of bases targeted in the panel or 97% of bases for whole exome sequencing;
- base calling with a base quality score of at least 30.

Germline Versus Somatic Variants

Mutations present in tumors but absent in the normal cells are referred to as *somatic*. Somatic mutations are major drivers of cancer behavior, but not all are causal. Indeed, the majority of somatic mutations observed in any individual tumor are most likely to be *passenger* mutations that play no functional role in the pathogenesis of the tumor but rather were expanded by an association with a driver mutation. The proportion of passengers to drivers differs dramatically from tumor type to tumor type. For example, tumors associated with tobacco (e.g., lung cancer) or sunlight exposure (e.g., melanoma) have very high mutation frequencies, with the majority of the observed mutations being "passengers." In contrast, many hematologic malignancies (e.g., acute lymphoblastic leukemia [ALL]) have relatively low mutation rates, and some cancers such as infant leukemias have extra ordinarily low rates.

It is important to recognize the difference between *germline* variants and acquired *somatic* variants in the cancer genome. Germline variants are present in all cells of the body and may contribute to disease risk. Germline risk variants can be common (i.e., seen in ≥5% of the human population), or they can be a rare observation, which has given rise to the concept of "common disease common variant" that is associated with low penetrance alleles in contrast to rare variants associated with disease that are likely to be highly penetrant.

Point Mutations or Single Nucleotide Variants

The most common type of genetic variants is *single-nucleotide variants*, also known as *point mutations*. Although not as common as point mutations, small somatic insertions or deletions *(indels)* that consist of the loss or gain of one or a few nucleotides that results in translational frameshifts, generally yielding loss-of-function alleles, are also seen. In the human population, it is estimated that every individual will harbor 50 to 100 unique coding mutations, which implies, if we are to prevent the miss-assignment of "private" germline variants as cancer-acquired somatic mutations, that we should compare the somatic genome of the tumor with its matched normal germline sequence.

Recently, computational models have been applied to large series of solid cancers, and signatures have been derived.[12] These signatures associated with mutations reflect their causative factors and have been termed *mutographs*. For example, G>T/C>A transversions are characteristic of tobacco-associated lung cancer, and C>T/G>A transitions are characteristic of ultraviolet radiation–associated skin cancers. The scientific rationale for mutographs is based on the preferential induction of a given nucleotide change within a 5′ and 3′ context, which is identified as a specific "signature."[13] Considering six possible substitutions in pyrimidine context, and four possible bases each at the neighboring 5′ and 3′ positions, there are 96 possible combinations of substitutions in a trinucleotide context. In addition to point mutations, many other molecular events participate in shaping the pathogenesis of cancer; whole-genome sequencing (WGS) techniques can interrogate the full repertoire of SNVs, CNAs, and SVs, and these can also provide information on the mutational processes operative in the early pathogenesis of multiple myeloma (MM) (Fig. 3.1).[14]

Structural Variation

Copy Number Abnormalities

Gains (amplifications) or losses (deletions) of chromosomal material at specific loci are recognized as playing an important role in the pathophysiology of cancer by either amplifying oncogene expression or decreasing tumor suppressor gene activity. In the germline, trisomy 21, for example, predisposes individuals to transient myeloproliferative disorders and acute megakaryoblastic leukemia.[15] Deletions at the *RB1* locus encoding the retinoblastoma gene or deletions of the *TP53* gene encoding the p53 tumor suppressor both predispose to the development of cancer.[16] In a landmark set of studies, it was shown that tumors from patients who inherit a mutant copy of the retinoblastoma tumor suppressor gene often have deletions of the remaining allele. This process has been termed *loss of heterozygosity*, and searching for such events in tumor samples has been used as a tool to identify genes involved in cancer progression. Similarly, amplification of genomic locus can play an important role in cancer progression.[17] For example, in multiple myeloma, amplification of a small amplicon at chromosome 1q23 is associated with adverse prognosis.[18]

Identifying CNAs has been done using a number of techniques. The original method was with metaphase *cytogenetic analysis*, which can identify abnormalities affecting large regions of the genome and was the basis for many important initial insights in hematologic malignancies. More recently, methods for assessing CNAs have advanced to include comparative genomic hybridization (CGH) and high-density single nucleotide polymorphism mapping arrays. However, these are being replaced by massively parallel genome sequencing. Although cytogenetic analysis remains a part of the diagnostic work-up for new cases of leukemia, it is likely that it will be replaced by NGS methods that also have the ability to detect point mutations, deletions/insertions, copy number changes, and chromosomal translocations, all at high resolution.

To identify statistically significant regions of CNAs, algorithms such as the genomic identification of significant targets in cancer (GISTIC) have been developed which can plot regions of amplification and deletion.[19]

Chromosomal Rearrangements

Translocations were among the very first genomic defects to be discovered in cancer because cytogenetic analysis of metaphase chromosome spreads was feasible on cell lines, especially for the acute leukemias. Chromosomal rearrangements include balanced and unbalanced translocations, inversions, and complex aberrations. Two basic types of translocations are common: those that result in fusion proteins involving two distinct genes and those that result in overexpression of an otherwise structurally normal gene. Translocations resulting in fusion transcripts (e.g., *ETV6/RUNX1* in ALL) generally involve chromosomal breakage within intronic regions of the two genes, with

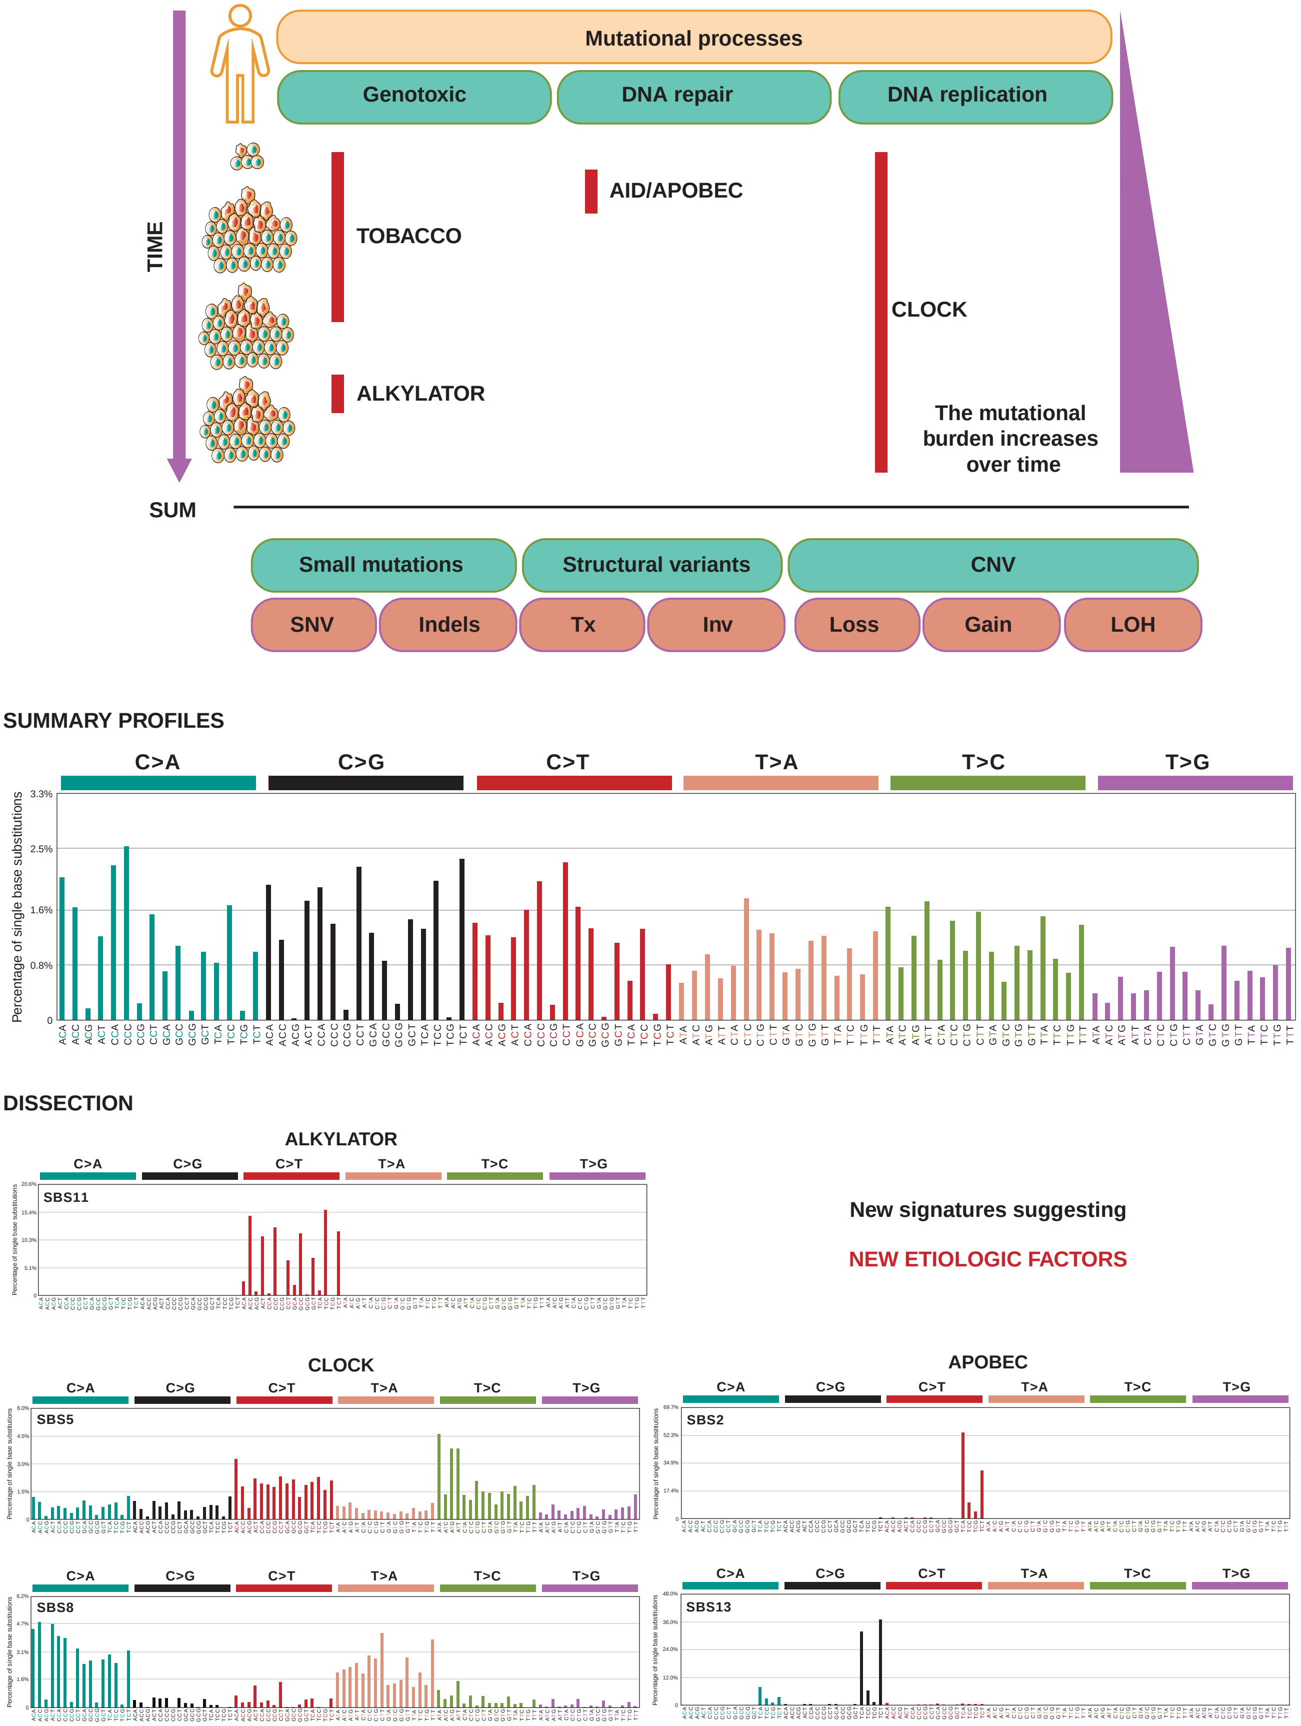

Figure 3.1 THE COMPLEXITY OF MUTATIONAL SIGNATURES. From the initiating, self-propagating cell to the relapsed and refractory stage, patients will acquire mutations secondary to different events that can be either tumor specific (e.g., AID or APOBEC), related to treatment or exposures (e.g., melphalan, cisplatinum, or even chemical exposure), or simply related to the aging process (e.g., Clock mutations). Tumors will represent a combination of these different signatures that can be teased out bioinformatically, with some remaining unexplained, suggesting they could be used to seek for novel etiologies.

in-frame fusion producing a new protein with a novel function being a result of the normal process of RNA splicing.[20]

In contrast, translocations resulting in overexpression typically involve the juxtaposition of a coding region next to a highly active promoter or enhancer region, such as an immunoglobulin region in B cells. For example, in follicular lymphoma, translocations frequently involve juxtaposition of the antiapoptotic gene *BCL2* to the immunoglobulin heavy chain enhancer region, leading to massive overexpression of *BCL2* RNA and protein.[21]

Complex chained rearrangements termed chromoplexy and regions of massive chromosomal rearrangement termed *chromothripsis* are more frequent than previously thought (Fig. 3.2).[22]

For the discovery of novel translocations, either whole genome sequencing or RNA-seq are the optimum methods. However, when a distinct fusion characterizes a specific disease (e.g., chronic myeloid leukemia [CML] and the BCR/ABL fusion), specific PCR reactions to detect it can be used for both diagnosis and response following therapy.[23]

Epigenomics

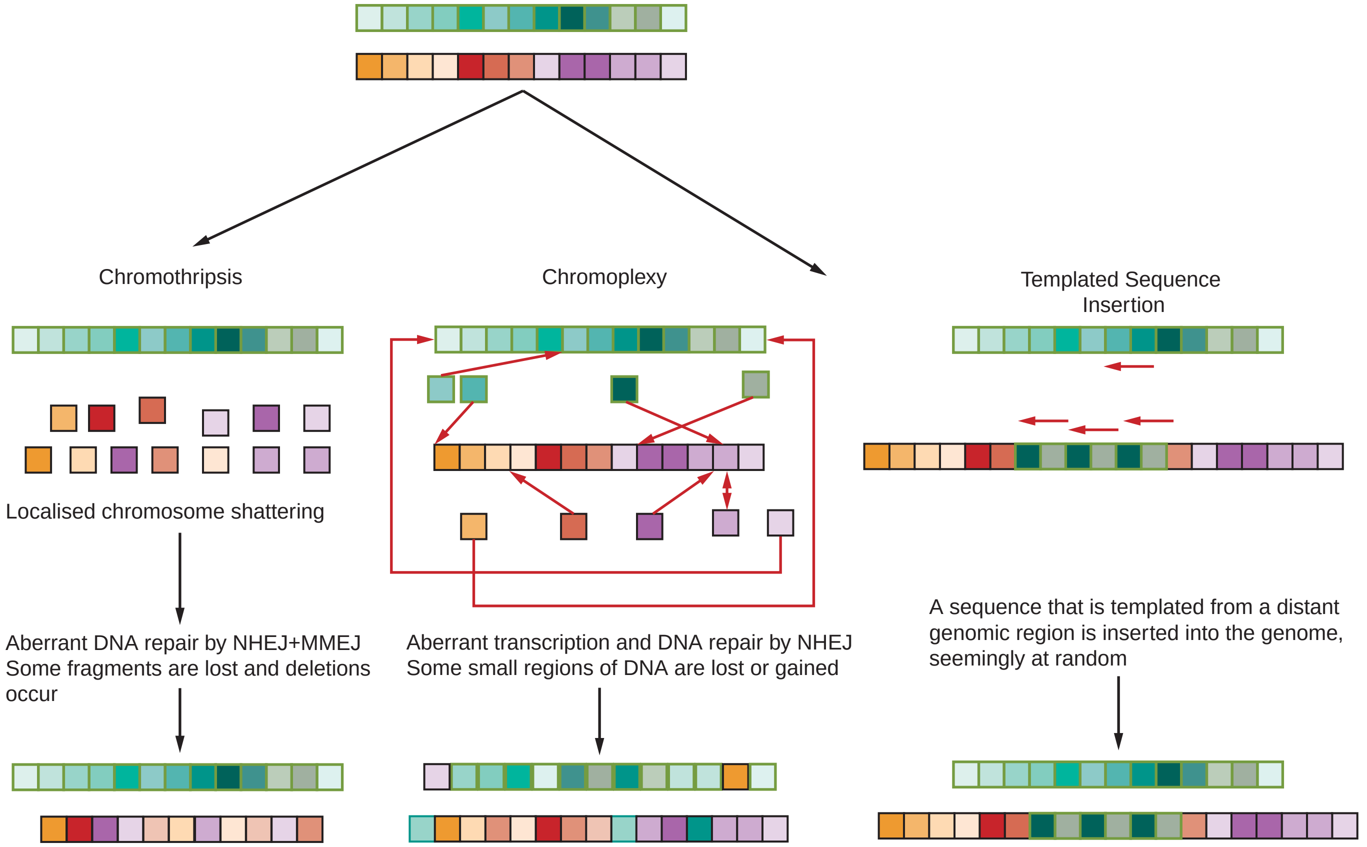
Epigenetic gene regulatory mechanisms play a critical role in the regulation of transcription, DNA repair, and replication. Several large-scale profiling efforts (e.g., through the National Institutes of Health ENCODE [Encyclopedia of DNA Elements] project) have used these technologies to annotate cancer cell lines and normal human and murine tissues, including hematopoietic subsets. Sequencing approaches to identify epigenomic changes include chromatin immunoprecipitation followed by sequencing (ChIP-seq), micrococcal nuclease (MNase) sequencing, DNAse sequencing (DNAse-seq), bisulfite sequencing and assay for transposase-accessible chromatin with high-throughput sequencing (ATAC-seq), and a range of chromatin capture techniques including HiC (high-throughput chromatin conformation capture). Massively parallel sequencing, coupled with bisulfite sequencing approaches, allows for genome-wide assessment of DNA methylation in development and disease.

Modifications to histones are orchestrated and tightly regulated by a group of enzymes called *chromatin regulators*. Perhaps one of the most striking results derived from genome-wide sequencing analyses in cancer is the frequency of somatic mutations in chromatin regulators, which account for up to 25% of all cancer drivers. With the use of NGS techniques combined with chromatin immunoprecipitation, it is now possible to comprehensively investigate the molecular mechanisms of epigenetic alterations and define their disease relevance. ChIP-seq can be used to map histone modifications that are associated with actively transcribed regions, repressed regions, or regions found at distal regulatory elements. Single-cell sequencing–NGS applications have been developed that allow DNA and RNA-seq of *single* cells derived from the tumor as well from the tumor microenvironment. A widely used approach takes advantage of packaging single cells into an emulsion droplet; when combined with a molecular barcoding of every RNA molecule from each single cell and then RNA-seq of the entire population, it is possible to precisely assign each RNA molecule to each cell, making it possible to determine the gene expression profile of each single cell. This approach allows in-depth dissection of the tumor and its subclonal structure. Perhaps the major use of this approach will be to identify the nature of the cells of the microenvironment and how it is altered by infiltrating tumor cells.

THE CLINICAL UTILITY OF GENOMICS IN HEMATOLOGIC MALIGNANCIES

Diagnosis

The use of genomics to enhance hematologic diagnosis was introduced following the identification of the disease-defining genetic event, the t(9;22) characteristic of CML. The use of this genetic



Chromothripsis
Chromoplexy
Templated Sequence Insertion
Localised chromosome shattering
Aberrant DNA repair by NHEJ+MMEJ
Some fragments are lost and deletions occur
Aberrant transcription and DNA repair by NHEJ
Some small regions of DNA are lost or gained
A sequence that is templated from a distant genomic region is inserted into the genome, seemingly at random

Figure 3.2 CARTOONS DEPICTING THE MAJOR COMPLEX STRUCTURAL VARIANTS. Chromothripsis, templated insertion, and chromoplexy.

diagnosis was expanded by the WHO classification of tumors of hematopoietic tissue,[3] which built diagnostic classifiers encompassing both histopathologic and genetic features (e.g., *JAK2* mutations in polycythemia vera, the t(15;17) in acute promyelocytic leukemia, 5q-syndrome in myelodysplasia) and gene expression profiles in lymphoproliferative malignancies (e.g., germinal center versus nongerminal center subtype of diffuse large B-cell lymphoma).

Beyond the refinement of diagnostic approaches, the application of genomic analysis can allow the early detection of hematologic malignancies using blood samples. Blood draws are considered safe and are less complicated and less expensive than a tissue biopsy; because they can easily be done at multiple time points, they can allow repeated assessment of the tumor over time.[24] This approach used *blood biopsies* that are based on the analysis of circulating tumor cells (CTCs), circulating tumor DNA, cell-free DNA (cfDNA), and circulating microvesicles/exosomes/apoptotic bodies in the blood. This material can provide an accurate representation of the tumor-acquired genetic changes simply by analyzing a vial of blood. An example is in angioimmunoblastic T-cell lymphoma where the G17V *RHOA* mutation in circulating DNA has been shown to be a useful diagnostic marker.[25] Genetics may also have a role in the generic work-up of cytopenia. Indeed, identifying genetic markers may help to discriminate various disease entities, some malignant or premalignant and some generally considered as benign (Fig. 3.3).

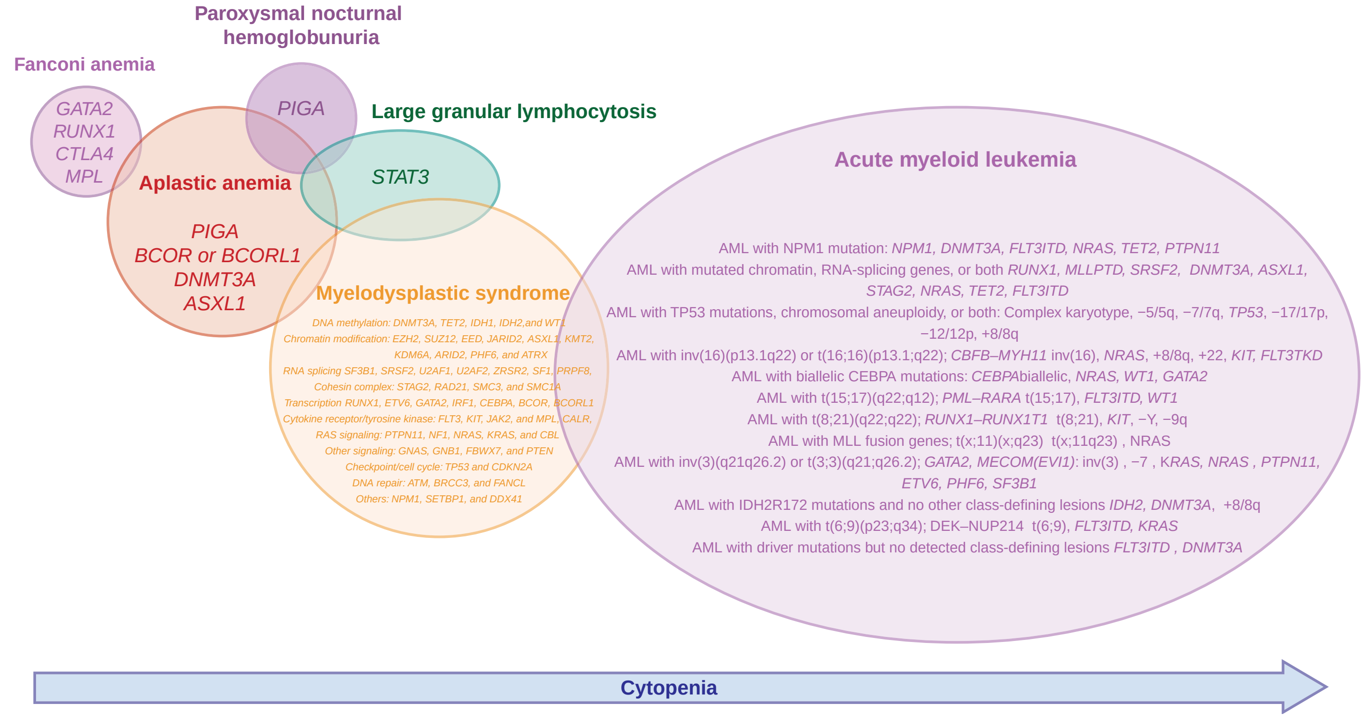
Precision Medicine and Molecularly Targeted Therapies

The application of genomics has allowed us to subcategorize blood diseases based on their molecular features and as such to develop novel precision treatment strategies. These strategies may rely upon using a therapy that directly targets the mutation (e.g., a BRAF inhibitor in a patient with a *BRAF* V600E-mutated neoplasm in hairy cell leukemia) or inform therapeutic decisions that are less directly related (e.g., not using ibrutinib in the germinal center subtype of diffuse large B-cell lymphoma).

There are numerous examples of precision medicine in hematologic malignancies. In ***myeloid malignancies***, the core-binding factor AML is defined by the presence of t(8;21)(q22;q22) or inv(16)(p13q22)/t(16;16)(p13;q22) that disrupts *RUNX1* (previously *CBFA/AML1*) or *CBFB* transcription factor functions. These variants are associated with a favorable outcome with chemotherapy and therefore are generally not assigned to allotransplant in first complete remission. Nonetheless, they may co-occur with activating *KIT* mutations, in which case they are associated with an adverse prognosis and may potentially be treated with tyrosine kinase inhibitors (TKIs) such as dasatinib[26] in an attempt to overcome the adverse prognosis. In ***diffuse large B-cell lymphoma***, building on the work of the Staudt group,[27] it has been possible to add COO subtypes to the mutation and refine the application of Bruton tyrosine kinase (BTK) inhibition (TKIs) (Fig. 3.4). The application of genomics in the clinic has led to a greater understanding of the complexities of multiple gene modifiers of outcome, including if an individual carries several driver mutations and which inhibitors should be targeted, as well as an appreciation of the statistical challenges of understanding such data.

Risk-Stratified Therapy

It has been more than a decade since the first proof-of-principle studies were published demonstrating the possibility of using gene expression profiling to subclassify cancer. These studies raised the possibility that gene expression signatures might be implemented in the routine clinical setting. In ***myeloma***, risk stratification has relied on iFISH analysis,[29] but it has been shown that risk scores based on gene expression signatures can outperform this strategy.[5] Currently, the gene expression based MyPRS test, based on a 70-gene signature, is approved for use in New York State but has not been widely taken up.[30] In ***chronic lymphocytic leukemia***, risk stratification and appropriate selection of treatment rely upon the identification of the mutation status at the immunoglobulin genes, cytogenetic factors (del(13q), del(11q), trisomy 12, del(17p)), and mutations (*TP53* mutation). Cases with loss of 17p and, more recently, mutation of TP53 are known to be chemoresistant and are treated differently with first line ibrutinib.[31] In ***acute myeloid leukemia***, the identification of cytogenetic subgroups derived from metaphase cytogenetic analysis has been used for many years to determine risk status and to assign



Paroxysmal nocturnal hemoglobunuria
Fanconi anemia
GATA2
RUNX1
CTLA4
MPL
PIGA
Large granular lymphocytosis
STAT3
Aplastic anemia
PIGA
BCOR or BCORL1
DNMT3A
ASXL1
Myelodysplastic syndrome
DNA methylation: DNMT3A, TET2, IDH1, IDH2,and WT1
Chromatin modification: EZH2, SUZ12, EED, JARID2, ASXL1, KMT2, KDM6A, ARID2, PHF6, and ATRX
RNA splicing SF3B1, SRSF2, U2AF1, U2AF2, ZRSR2, SF1, PRPF8,
Cohesin complex: STAG2, RAD21, SMC3, and SMC1A
Transcription RUNX1, ETV6, GATA2, IRF1, CEBPA, BCOR, BCORL1
Cytokine receptor/tyrosine kinase: FLT3, KIT, JAK2, and MPL, CALR,
RAS signaling: PTPN11, NF1, NRAS, KRAS, and CBL
Other signaling: GNAS, GNB1, FBWX7, and PTEN
Checkpoint/cell cycle: TP53 and CDKN2A
DNA repair: ATM, BRCC3, and FANCL
Others: NPM1, SETBP1, and DDX41
Acute myeloid leukemia
AML with NPM1 mutation: NPM1, DNMT3A, FLT3ITD, NRAS, TET2, PTPN11
AML with mutated chromatin, RNA-splicing genes, or both RUNX1, MLLPTD, SRSF2, DNMT3A, ASXL1, STAG2, NRAS, TET2, FLT3ITD
AML with TP53 mutations, chromosomal aneuploidy, or both: Complex karyotype, −5/5q, −7/7q, TP53, −17/17p, −12/12p, +8/8q
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); CBFB–MYH11 inv(16), NRAS, +8/8q, +22, KIT, FLT3TKD
AML with biallelic CEBPA mutations: CEBPAbiallelic, NRAS, WT1, GATA2
AML with t(15;17)(q22;q12); PML–RARA t(15;17), FLT3ITD, WT1
AML with t(8;21)(q22;q22); RUNX1–RUNX1T1 t(8;21), KIT, −Y, −9q
AML with MLL fusion genes; t(x;11)(x;q23) t(x;11q23) , NRAS
AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); GATA2, MECOM(EVI1): inv(3) , −7 , KRAS, NRAS , PTPN11, ETV6, PHF6, SF3B1
AML with IDH2R172 mutations and no other class-defining lesions IDH2, DNMT3A, +8/8q
AML with t(6;9)(p23;q34); DEK–NUP214 t(6;9), FLT3ITD, KRAS
AML with driver mutations but no detected class-defining lesions FLT3ITD , DNMT3A
Cytopenia

Figure 3.3 EXAMPLE OF THE ROLE OF GENOMICS IN THE WORK-UP OF CYTOPENIA. Among the major causes of cytopenia, several disease entities can be identified. Despite clinical (usually depth of cytopenia, age), morphologic, and flow differences, molecular studies can help to differentiate between these similar entities. *(Modified from Young NS. Aplastic anemia. N Engl J Med. 2018; 379:1643–1656.)*

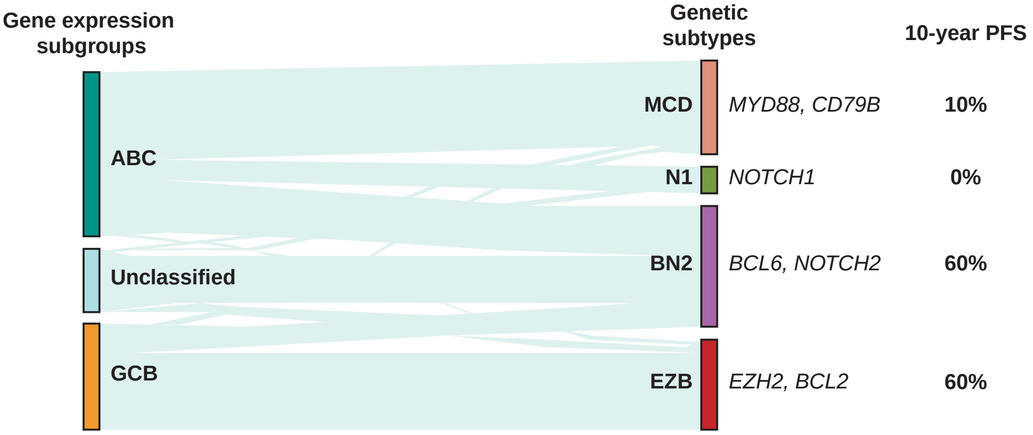


Figure 3.4 THE MOLECULAR DIAGNOSIS OF DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL). Gene expression subgroups first stratified DLBCL patients based on their cell of origin, whether germinal center B cell, activated B cell, or unclassified. By combining genetic events, this classification can be refined and four subgroups identified, characterized by mutational patterns and prognostic features termed N1 (for *NOTCH1*), MCD (for *MYD88* and *CD79B*), BN2 (for *BCL6* and *NOTCH2*), and EZB (for *EZH2* and *BCL2*) (adapted from Schmitz et al.[28]); it can guide personalized treatment strategies with agents such as lenalidomide, ibrutinib, and tazemetostat.

patients to receive allogeneic transplantation or not. This approach in acute leukemia has been further refined by the European Leukemia Network (ELN), who introduced the use of mutations such as biallelic *CEBPA*, monoallelic *NPM1, RUNX1, ASXL1, or TP53* and internal tandem repeats at the *FLT3* locus.[32]

Response-Adapted Therapy and Minimal Residual Disease Monitoring

Combination chemotherapeutic regimens have been a great success in the management of hematologic malignancies, leading to deep and durable responses, including cures, in some settings. The ability to monitor response and to adjust therapy based upon the level of response opens the potential for response-adapted therapeutic approaches. This response-adapted approach relies upon the development of sensitive testing strategies able to detect and monitor tumor cells below the level of clinical detection and has been termed minimal residual disease (MRD) monitoring. Classically, flow cytometry has been used, but it is restricted by sample requirements, disease type, and technical limitations. Other approaches have been developed based on molecular approaches based either on PCR or NGS.

Response-adapted therapy was developed initially in CML. The initial approach to detect response was cytogenetics but lacked sensitivity, as did iFISH. Quantitative reverse transcription PCR (QRT-PCR) was able to detect the Bcr-Abl RNA fusion gene down to a level of 1 tumor cell in 10^6 normal cells and provided an excellent tool to monitor therapy in patients undergoing treatment with TKIs. In this setting the achievement of MRD negativity is one of the critical clinical end points. More recently, this end point has been used to design MRD-driven TKI discontinuation trials (e.g., the STIM study).[33] In this trial, 38% of patients remained in treatment-free remission at 60 months, without molecular recurrence. Patients eligible for discontinuation had to achieve MRD negative as measured by QRT-PCR that was maintained for at least 2 years. Across TKI discontinuation trials, treatment-free remission rates after maintaining deep molecular response for at least 1 year ranged from 40% to 60%.[34]

At around the same time as monitoring of CML was being developed, in childhood acute lymphoblastic leukemia high remission rates and cures were being achieved. Despite this high cure rate, a substantial proportion of cases relapsed, which was addressed by the application of MRD monitoring. A sensitive clonality-based test using rearrangement of the immunoglobulin gene Ig loci was developed for application in lymphoid tumors. Applying this approach in ALL showed that the failure to fully eradicate the disease to a sensitivity level of one tumor cell in a million normal cells at a prespecified time point during treatment was associated with high rates of relapse, allowing the potential to modify the therapy early on in therapy.

The early technical approach to clonality detection relied on Southern blotting and was very time consuming but has now been replaced by NGS of T-cell and B-cell receptor genes. This sequencing approach targets a limited number of genomic regions that are involved in V(D)J recombination of the T-cell and B-cell receptors, thus allowing identification of monoclonal B and T cells, which define the malignant tumor cells. Because these regions are sequenced to great "depth," malignant clones can be detected even if they occur with a frequency of only 1 in 10^5 to 10^6.

One of the approved indications for this MRD detection with NGS-based clonality testing is multiple myeloma, the therapy of which has been transformed over the past 15 years with the advent of many new therapeutic agents. In younger patients after autologous stem cell transplantation, a meta-analysis has provided strong evidence for improved outcomes in patients achieving MRD-negative responses. However, there remains debate around the optimum level of sensitivity, with the optimum level being one tumor cell in 10^6 normal cells. There is also debate about the optimum testing strategy to be used, either flow cytometry or DNA-based clonality assays based on NGS.[35] These debates will be resolved as the approach goes through evaluation by the FDA for application as a legitimate trial end point.

Pharmacogenomics

Pharmacogenomics aims to apply genome variants that reflect drug behavior, typically via alterations in drugs' pharmacokinetics (absorption, distribution, elimination, metabolism) or via accentuation of drugs' pharmacodynamics (modifying the pharmacologic effects of a drug target). Classical examples of pharmacogenomics approaches in hematology include methylene tetrahydrofolate reductase *(MTHFR)* genotypes that affect the safety and efficacy of 6-mercaptopurine and methotrexate therapies[36] in leukemia and lymphoma. Similarly, a nonsynonymous SNP in the *OCT2* gene (rs316019), the organic cation transporter, in lymphoma or myeloma has been associated with reduced cisplatin-induced nephrotoxicity.[37,38]

To understand interpatient responses to drugs is pressing in oncology, where anticancer agents have narrow therapeutic indices and severe side effects. Pharmacogenomic approaches are also being used to determine the safety and efficacy of novel, targeted treatments, not only by analyzing the presence of a target tumor biomarker such as *ALK* fusions for crizotinib or *IDH2* mutations for enasidenib but also by determining their safety profile. For instance, belinostat, a histone deacetylase inhibitor drug approved in T-cell lymphoma, is predominantly metabolized by UGT1A1, which is polymorphic and requires genotype-based dose adjustment to normalize belinostat exposure, allowing for a better, more tolerable therapeutic experience.[39]

THE CLINICAL UTILITY OF GENOMICS IN BENIGN HEMATOLOGY

The diagnosis of inherited disorders in the early years of life and later in life can be very complex. The increasing knowledge of the genetic basis for many of the inherited disorders affecting the blood, together with the power of genomic approaches, has opened the way for the relatively simple screening for such disorders. The optimum approach for this is not fully established as yet but can be done by either the identification of single gene variants or multiple variants in a specific disease area, or by sequencing the entire genome. Sequencing the entire genome is the most comprehensive approach but at this stage brings with it issues of data handling, analysis, and ethics associated with the potential to sequence everybody in their early life. However, it is likely that such approaches will come into widespread use over time.

Some examples of the potential approaches in hematologic disorders are given as follows:

The Hemoglobinopathies

The genetic basis for the hemoglobinopathies and thalassemias is well known, and many causative genetic variants can be detected using simple polymerase chain reaction (PCR) approaches. Some uncommon mutations (Hb Q-India, HbNedlands, Hb Queens Park) require specific primers, but the approach to detecting such disorders is readily applied during prenatal screening. Deletions and mutations can readily be detected using allele-specific PCR for mutations or Gap-PCR for deletions, which use primers that bind to both sides of a deletion and can be used to successfully diagnose α-thalassemias, resulting from variable-sized deletions of α-globin gene.

Clotting Disorders

Genomic techniques can be helpful to refine thrombotic risk prediction. Current approaches focus on five common genetic risk factors for venous thromboembolism, including antithrombin, protein C, and protein S deficiency; factor V Leiden; and the G20210A prothrombin gene variant. Although the diagnosis of these thrombophilias is routinely based on functional assays of the coagulation cascades, the use of genetic testing to augment this approach can be useful. To date, genotyping has not replaced plasma-based assays for diagnostic purposes, with the exception of the prothrombin gene variant. Testing for activated protein C resistance remains controversial, even with the second-generation plasma assays using factor V–deficient plasmas. Some institutions simply do factor V Leiden DNA testing, whereas others use a less expensive plasma-based PCR assay and do DNA testing only for validation.

Disease with Rare Penetrant Variants Involving Multiple Loci

The ability of NGS to capture and analyze multiple gene loci has given it the ability to screen multiple loci in a single test. This approach relies upon a knowledge of the genetic basis of the disorder and the development of a specific testing panel. Thus genome-wide targeted exon capture followed by high-throughput DNA sequencing can provide an unbiased analysis of coding exons and is applicable to diseases associated with significant genotypic variability caused by mutations in numerous genes that result in the same clinical phenotype. One example of such a disease is Fanconi anemia, a heterogeneous bone marrow failure syndrome associated with defective DNA repair associated with cancer predisposition and congenital anomalies. It is inherited primarily as an autosomal recessive fashion, with more than a dozen Fanconi genes having been described. Application of exome sequencing to Fanconi patients has identified a variety of mutations in Fanconi-associated genes, several of which are novel, such as the *XRCC2*, one of five *RAD51* paralogs that act nonredundantly in the pathway of homologous recombination repair.[40] The increasing knowledge of the genetic basis for such disorders will allow the design and application of increasingly refined panels in a clinical setting. Currently the approach is readily applicable and easier to apply than sequencing the entire genome; however, as technology improves, it is likely that whole genome sequencing will replace looking for variants already described.

Common Low Penetrance Risk Variants

Inherited variants can modify disease response by the inheritance of common genetic variants with low penetrance. These inherited variants have been investigated by genome-wide association studies (GWASs), which often require thousands of patient samples to have sufficient power to detect statistically significant associations. Many GWASs have been performed, attempting to identify common variants contributing to complex disease. An example is the sequencing of candidate genes near loci implicated in fetal hemoglobin (HbF) level variation, which showed that rare variants in *MYB* to be associated with HbF levels.[41]

The approach of identifying common variants that modify responses of specific pathways has been extensively explored in the coagulation cascades. Numerous clinical studies have addressed genetic variation at *VCORC1* and *CYP2C9* to identify risk in the use of vitamin K antagonists for anticoagulation.[42] These approaches have been extended further to define genetic risk scores associated with venous thromboembolism (VTE) bAe with the goal of personalizing anticoagulation therapy for prevention of recurrent VTE, but much more development is required before such approaches are clinically useful. Similar GWAS approaches have been evaluated for antiplatelet agents. Clopidogrel, a P2Y12 inhibitor, is activated by the cytochrome P450 system. Patients carrying the CYP2C19*2 allele metabolize clopidogrel poorly and are good candidates for alternative P2Y12 inhibitors due to their higher risk of arterial thrombosis.[43]

APPROACHES TO THE DEVELOPMENT OF MOLECULAR TESTING

Important considerations for the application of genomic testing strategies in the clinic are the models by which they will be applied and how to store and analyze the data generated. The use of DNA-based testing has advantages over RNA-based approaches. In comparison with RNA-based analysis, DNA-based diagnostics have the advantage of being more definitive in detecting target variants (e.g., the presence of a mutation [A, G, C, or T]) as opposed to the detection of the relative abundance of a particular transcript.

The model by which testing is done is also relevant, with centralized testing approaches where all samples are sent to a set of national laboratories where testing and quality control are managed or whether it is done locally, taking advantage of infrastructure in pathology departments. The latter approach requires the use of defined machinery and diagnostic kits providing the means of maintaining quality control. Perhaps the most important of all is whether whole genome sequencing approaches that are agnostic to the clinical question being asked are used or whether it is optimum to use panels designed for a specific clinical question. Clearly, data handling and analysis requirements influence the approach used, as do statistical analysis and the generation of false-positive results.

The uptake of molecular diagnostics has been slow, which can be explained by a number of features. Financial reimbursement by health insurance payers has been difficult, making it important to demonstrate the utility, and measurable patient benefit is critical. Validation and regulatory approval are required to develop valid diagnostic tests, and for this to be done successfully the test must be applied to large numbers of patients; in many cases, such series of patients simply do not exist. Furthermore, the academic publishing system tends to reward *initial* discoveries, but the essential follow-up *validation* studies tend to be valued less and therefore are more difficult to fund. The economics of reimbursement for molecular diagnostics have in general not been favorable, thus discouraging companies from making major investments in the validation and commercialization of promising diagnostic tests. It is likely that diagnostic tests will command more of a premium in the future as a mechanism to use expensive therapeutics only in patients likely to benefit, but the time required for this to evolve is uncertain.

DNA sequencing is now routine at many academic centers and is increasingly being used to drive precision medicine by suggesting potential therapies based on an individual patients' genetic profile. The development of precision medicine will drive the application of genomic testing. With genomic, transcriptomic, and epigenetic data already available for the most common hematologic and malignant diseases and with new data being generated at an ever-increasing rate, there will be great opportunity for diagnostic and therapeutic development. The integration of genomic and other high-throughput sequencing approaches will continue to be one of the greatest challenges and opportunities in medicine in the decade ahead.

CHAPTER 4

REGULATION OF GENE EXPRESSION IN HEMATOLOGY

Stephanie Halene, Toma Tebaldi, and Gabriella Viero

INTRODUCTION

The function of a cell is not only determined by the sum of the specific RNAs and proteins expressed but also by their metabolism, modification, and localization. To understand how a cell behaves, one must understand how the expression of genes, translation of transcripts, and processing of proteins are regulated.

Through concerted regulation of these processes, hematopoietic stem cells (HSCs) maintain a balance between quiescence and differentiation to mature blood cell types; erythroid progenitors produce vast quantities of hemoglobin; myeloid cells generate granules of immune responses; lymphocytes control immunoglobulin levels; and platelets regulate levels of thrombotic receptors.

Aberrant gene expression and RNA metabolism can result in hematologic disorders such as lymphomas, leukemias, and myelodysplastic and myeloproliferative syndromes. Furthermore, mutations in elements of the ribosomal machinery result in bone marrow failure syndromes. Understanding the process behind RNA and protein synthesis, trafficking, and degradation is crucial for the diagnosis and treatment of hematologic disorders.

This chapter will present the foundation necessary to understand the process of gene expression through RNA synthesis and processing, including transcription, splicing, modification, nuclear export, localization, stability and translation as well as posttranslational protein modification, targeting, and localization.

The first step of gene expression is transcription, where RNA polymerases decode the DNA using specific start and stop signals to synthesize RNA (Fig. 4.1). In the subsequent step, splicing removes introns, portions of the RNA that do not code for protein. The RNA is "capped" at the 5′ end and supplied with a poly-A tail at the 3′ end; RNA is also modified cotranscriptionally providing an additional layer for regulation of its stability and localization. RNA modifications define the *epitranscriptome* in analogy to DNA and histone modifications (called the *epigenome*). Next, the spliced RNA is targeted for export out of the nucleus and into the cytoplasm, where ribosomes translate the RNA into protein products (see Fig. 4.1). Protein synthesis occurs in the cytoplasm and generates a great variety of products endowed with a wide spectrum of functions. The complete set of proteins produced by a cell is called the proteome and is responsible for the remarkable diversity in cell specialization that is typical of metazoan organisms. To be functional, proteins need to be properly folded, assembled, often modified, and transported to their specific destination. The cells' interior harbors several membrane-bound organelles, such as the mitochondria, peroxisomes, nucleus, and endoplasmic reticulum (ER), to which the proteins may be targeted. In addition, membraneless organelles have been identified both in the nucleus and in the cytoplasm, including nucleoli, Cajal bodies, P-bodies, and stress granules. These organelles exist as liquid droplets within the cell and arise from the condensation of cellular material in a process termed liquid-liquid phase separation (LLPS).

This chapter briefly describes gene expression from start to end, exploring both classic and emergent regulatory mechanisms and connecting them with hematologic disorders.

REGULATION OF TRANSCRIPTION

Each cell in the human body contains approximately 60,000 genes (approximately 20,000 protein coding, 18,000 long noncoding, 7500 small noncoding and 14,500 pseudogenes). Only 1% to 2% of human DNA actually serves to code for proteins; the remaining part is prevalently involved in regulating DNA replication and gene expression across cell types and developmental stages. Together these regulatory sequences determine in which cell, at what time, and in what amount the gene is converted into the corresponding protein.

RNA Polymerase Binding and Regulation by Transcription Factors

RNA polymerase synthesizes RNA from a DNA template. For transcription to begin, RNA polymerase must attach to a specific DNA region at the beginning of a gene, known as *promoter*. Transcription factors control access of and frequently recruit RNA polymerases to promoter regions. Promoters can additionally function together with other more distant regulatory DNA regions, such as *enhancers* or *repressors* to further control the level of transcription of a given gene. *Insulator* regions in the genome protect genes from influences from regulation of neighboring genes. Multiple enhancer sites may tune the transcription of one gene, and each enhancer may be bound by more than one transcription factor, increasing the complexity of transcriptional regulation. Enhancers are often the major determinant of transcription of developmental genes in the differing lineages and stages of hematopoiesis. Genes can have more than one transcription start site, giving rise to RNA molecules starting with distinct sequences.

RNA is heterogeneous and stretches of genomic DNA may encode for more than one RNA or more than one type of RNA. Most eukaryotic RNA genes, especially messenger RNAs (mRNAs), contain a basic structure consisting of alternating coding exons and noncoding introns, subsequently dealt with in the splicing process.

While most RNAs in the cell are encoded by chromosomes in the nucleus, several mitochondrial proteins are encoded by the mitochondrial genome, often referred to as mtDNA. Transcription of the different classes of RNAs in eukaryotes is carried out by three different RNA polymerase enzymes. RNA polymerase I synthesizes the ribosomal RNAs (rRNAs), except for the 5 S species. RNA polymerase II synthesizes the mRNAs and some small nuclear RNAs (snRNAs) involved in RNA splicing. RNA polymerase III synthesizes 5 S rRNA and transfer RNAs (tRNAs). Transcription levels are finely tuned by the binding strength of the RNA polymerase to the promoter region at the beginning of a given gene, the interaction between activating and inhibiting transcription factors that bind to the given promoter, and transcriptional regulatory domains such as the enhancers or silencers mentioned previously.

Gene-specific transcription factors are sequence-specific DNA binding proteins that can be modified by cell signals. Numerous genetic diseases are associated with mutations in a gene's coding

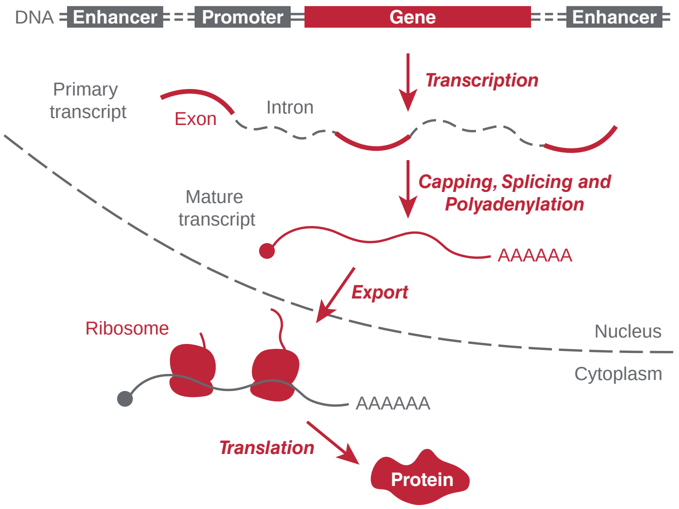

Figure 4.1 OVERVIEW OF GENE EXPRESSION FROM DNA TO PROTEIN VIA RNA. Gene expression is a complex process requiring multiple and strictly regulated steps: transcription of the primary transcript, RNA maturation through capping, splicing and polyadenylation, export to the cytoplasm, and translation into protein.

region, promoter, or enhancers. In β-thalassemia, mutations can occur in the promoter region, the enhancer region, or the coding region of the gene. Mutations can involve single nucleotide substitutions, small deletions, or insertions and can heavily affect transcription, RNA splicing or stability, translation, and ultimately protein availability or functionality. Regulation of transcription is fundamental during T-lymphocyte differentiation, which requires binding of multiple activating transcription factors, such as lymphocyte enhancer factor (LEF)-1, GATA binding protein 3 (GATA)-3, and ETS proto-oncogene (ETS)-1, to the T-cell receptor alpha (TCRA) gene enhancer.

Mutations in promoter sequences that result in decreased transcription factor binding, and therefore less RNA polymerase binding, ultimately lead to decreased gene expression. One of the best examples of a mutation in a transcription factor binding site associated with a human disease is in the factor IX gene. The transcription factor hepatocyte nuclear factor 4 alpha (HNF4α) is required to bind to the factor IX promoter before this gene can be transcribed.[1] Patients with a mutation in the HNF4α binding site can develop hemophilia B, an X-linked recessive bleeding disorder primarily affecting males (Fig. 4.2).

Many transcription factors, such as signal transducer and activator of transcription (STAT) proteins, require phosphorylation to bind DNA. Since transcription factors can be targeted by kinases and phosphatases, phosphorylation can effectively integrate information carried by multiple signal transduction pathways, thus providing versatility and flexibility in gene regulation. For example, the Janus kinase (JAK)-STAT pathway is widely used by members of the cytokine receptor superfamily, including those for granulocyte colony-stimulating factor (G-CSF), erythropoietin, thrombopoietin, interferons, and interleukins. Normally, ligand-bound growth factor receptors lead to JAK2 phosphorylation, which then activates STAT, also by phosphorylation. Activated STAT then dimerizes, translocates to the hematopoietic cell nucleus, binds DNA, and promotes transcription of genes for hematopoiesis. Alteration of JAK2, such as a V617F mutation, results in a constitutively active kinase capable of driving STAT activation. This leads to constitutive transcription of STAT target genes and results in myeloproliferative disorders such as polycythemia vera.

Regulation of Transcription by Chromatin

The ability of transcription factors and RNA polymerases to access specific promoters and transcribe genes is also regulated by the packaging of DNA by proteins and RNA, together forming the *chromatin*. Chromatin can package DNA tightly *(heterochromatin)* or loosely *(euchromatin)*. In *euchromatin*, RNA polymerases can freely bind to DNA and genes are actively transcribed. In *heterochromatin*, DNA is tightly packaged, protected from the transcription machinery, sequestering genes away from transcription. The basic unit of chromatin is the nucleosome, which contains eight histone proteins packaging 146 base pairs of DNA. Histones can be extensively modified to regulate the accessibility of the DNA to the transcriptional apparatus (see Chapter 3). Histones can be chemically modified by acetylation, methylation, phosphorylation, or ubiquitination. In general, acetylation opens the nucleosome to increase transcription, whereas phosphorylation marks damaged DNA. Histone methylation can either open chromatin to increase transcription or close it to repress transcription, depending on where the histone is methylated. Transcription factors can themselves recruit histone-modifying enzymes that further regulate transcription. In hematopoiesis, transcription factors, including GATA-1, EKLF, NF-E2, and PU.1, recruit histone acetyltransferases (HATs) and histone deacetylases (HDACs) to promoters of their respective target genes, leading to addition or subtraction of acetyl groups from histones, that in turn alters chromatin structure and accessibility for transcription.[2] GATA-1, a gene essential to erythroid maturation and survival, directly recruits HAT complexes to the β-globin locus to stimulate transcription activation.

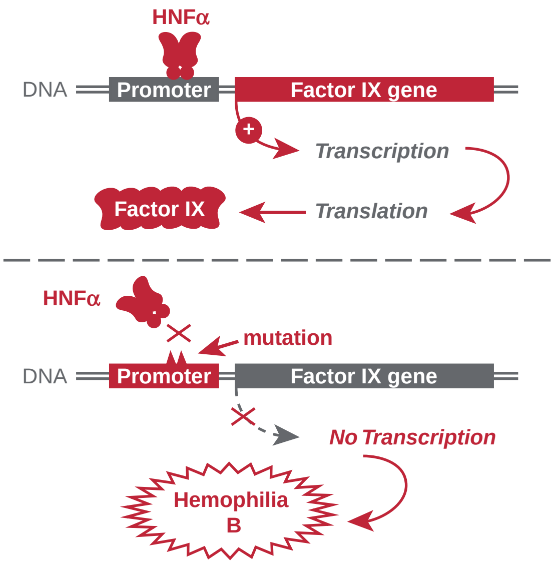

Figure 4.2 ROLE OF TRANSCRIPTION FACTORS IN THE REGULATION OF EUKARYOTIC GENE EXPRESSION. Upper panel: schematic diagram of the DNA region containing the locus of the coagulation factor IX gene and its promoter, containing a binding site for the HNFα transcription factor. Lower panel: mutations in either the promoter region or in the HNFα transcription factor reduce the expression of factor IX, leading to bleeding disorders such as hemophilia B.

Chromatin remodeling is mediated by a family of proteins with switch/sucrose nonfermentable (SWI/SNF) domains. These proteins use adenosine triphosphate (ATP) hydrolysis to shift the nucleosome core along the length of the DNA, a process also known as *nucleosome sliding*. By sliding nucleosomes away from a gene sequence, SWI/SNF complexes can activate gene transcription. SWI/SNF proteins also contain helicase enzyme activity, which unwinds the DNA by breaking hydrogen bonds between the complementary nucleotides on opposite strands. By unwinding the DNA into two single strands, the DNA can then be read by RNA polymerases in the direction 3′ to 5′, allowing RNA polymerase to produce an antiparallel RNA strand. The SWI/SNF complex has been shown to be active in the DNA damage response and is also responsible for tumor suppression. These processes are described in further detail in Chapter 2.

Regulation of Transcription by DNA Modification

DNA can also itself be chemically modified to amplify or suppress transcription. CpG sites within gene promoter regions can be chemically modified by methylation enzymes called DNA methyltransferases (DNMTs), which decrease DNA binding of RNA polymerase and associated transcription factors. Hypermethylation has been observed in bone marrow cells of patients with myelodysplastic syndromes (MDSs), and the degree of DNA hypermethylation correlates with disease stage. In MDSs, the promoters of genes that are important for myeloid differentiation are hypermethylated, repressing their transcription and inhibiting proper maturation of the myeloid lineages. Hypomethylating agents such as azacitidine and decitabine can induce remission and may prolong survival in some MDS patients.

The regulation of gene expression by modification of chromatin conformation or DNA itself is termed *epigenetic* because it tunes cell function without altering the nucleotide sequence of the DNA. Regulation and function of the epigenome and their role in hematopoiesis and diseases thereof are described in Chapter 3 and reviewed in Cullen et al.[3] Examples of hematologic malignancies driven by disordered epigenetic regulation include MDSs and acute myeloid leukemia (AML), with mutations in the *DNMT3A* gene observed in approximately 5% of MDSs and approximately 20% of AML cases. DNMT3A mutations confer a worse prognosis in AML. The ten-eleven-translocation methylcytosine dioxygenase member, TET2, catalyzes hydroxymethylation of cytosines in DNA and results in demethylation of DNA; TET2 is mutated in AML, MDSs, chronic myelomonocytic leukemia (CMML), and other myeloproliferative neoplasms (MPNs), and all mutations represent loss-of-function mutations. Both DNTM3A and TET2 mutations, together with mutations in other chromatin modifiers such as ASXL1, can widely regulate gene expression and are often present in clonal hematopoiesis, preceding onset of frank malignancy.

RNA Proofreading

Before a final mRNA product is made that can be translated, several proofreading regulatory steps must take place. The RNA polymerase may not even clear the promoter and slip off, producing truncated transcripts. Once the nascent transcript reaches approximately 23 nucleotides, the RNA polymerase no longer slips off, and full transcript elongation can occur. RNA polymerase then continues to traverse the template DNA strand, using ATP while complementarily pairing bases and forming the phosphodiester-ribose backbone. Many RNA transcripts may be rapidly produced from a single copy of a gene, as multiple RNA polymerases can transcribe a gene simultaneously, spaced out from one another. An important proofreading mechanism during elongation allows the substitution of incorrectly incorporated bases or editing of bases for other purposes, usually by permitting short pauses during which the appropriate RNA editing factors can bind. RNA editing mechanisms in mRNAs include nucleoside modifications of cytidine to uridine (C-U) and adenosine to inosine (A-I) by deamination, as well as nucleotide insertions and additions without a DNA template by protein complexes called *editosomes*. Adenosine-to-inosine (A-to-I) modifications make up nearly 90% of all editing events in RNA. The deamination of adenosine is catalyzed by the double-stranded RNA(dsRNA)-specific adenosine deaminase (ADAR). The deamination of adenosine to inosine disrupts and destabilizes dsRNA base pairing with multiple possible outcomes, such as reduced formation of small interfering RNAs (siRNAs) but also labeling of RNA as self and prevention of activation of an innate immune response. Studies in hematopoiesis and leukemia have elucidated the critical roles of A-to-I editing.[4]

Another important repair mechanism is transcription-coupled nucleotide excision repair, where RNA polymerase stops transcribing when it comes to a bulky lesion in one of the nucleotides in the gene. A large protein complex excises the DNA segment containing the bulky lesion, and a new DNA segment is synthesized to replace it, using the opposite strand as a template. The RNA polymerase then resumes transcribing the gene. However, in general, RNA proofreading mechanisms are not as effective as in DNA replication, and transcription fidelity is generally lower.

REGULATION OF RNA PROCESSING: CAPPING, SPLICING, AND POLYADENYLATION

After a eukaryotic gene is transcribed, the primary transcript is modified to protect it from degradation and target it for export into the cytoplasm and eventually translation to protein (see Fig. 4.1). These modifications generate the mature transcript and include capping, splicing, and polyadenylation. Capping occurs shortly after the start of transcription, when a modified guanine nucleotide is added to the 5′ end of the mRNA. This terminal 7-methylguanosine residue is necessary for proper attachment to the 40 S ribosome subunit during translation initiation. It also protects the RNA from endogenous ribonucleases that degrade uncapped RNA, which is often viral in origin. RNA polymerases do not terminate transcription in an orderly manner. They tend to be processive, yet the cell cannot tolerate a population of mRNAs that are enormous in size. Therefore mRNAs have a signal, the sequence AAUAA, that defines the end of the transcript. In general, ribonucleases cut mRNAs shortly after that signal, and a chain of several hundred adenosine residues, the poly(A), is added to the free 3′ transcript end. RNA cleavage and synthesis of the poly(A) tail require binding of specific proteins, including cleavage/polyadenylation specificity factor (CPSF), cleavage stimulation factor (CstF), polyadenylate polymerase (PAP), polyadenylate binding protein 2 (PAB2), cleavage factor I (CFI), and CFII, that function to catalyze cleavage and protect the mRNA from exoribonucleases. The poly(A) tail increases RNA stability and assists in RNA export to the cytoplasm and translation. Mutations in the poly(A) signal can result in hematologic disease. For example, there are thrombophilic patients with a mutation in the polyadenylation signal in the prothrombin gene that increases the stabilization of this mRNA, resulting in higher prothrombin protein levels and increased thrombosis.

Before the mRNA is exported from the nucleus to be translated into protein, introns must be removed and the exons reconnected (see Fig. 4.1). In complex multicellular organisms such as vertebrates, introns are approximately 10-fold longer than the exons. The sequence and length of introns varied rapidly over evolutionary time. The process of removing introns, termed *splicing*, requires a series of reactions mediated by the spliceosome, a dynamic complex formed anew on its substrate from 5 snRNAs and approximately 100 proteins to form small nuclear ribonucleoproteins (snRNPs).[5] Recent critical advances in cryoelectron microscopy have shed light on the dynamics of assembly and disassembly of the spliceosome and the splicing process.[6] Canonical splicing uses the major spliceosome and accounts for more than 99% of splicing. The major spliceosome is composed of the nuclear active snRNPs U1, U2, U4, U5, and U6 along with multiple specific accessory proteins, such as U2AF and SF1. The spliceosome complex recognizes the dinucleotide GU at the 5′ end of an intron and an AG at the 3′ end (Fig. 4.3). Splicing can also occur cotranscriptionally and is regulated by chromatin factors that regulate transcription.[7] As transcription proceeds, an RNA lariat structure forms as intermediate, connecting intron ends, providing for both excision of the intron and proper alignment of the ends of the two bordering exons to allow precise ligation. When the intronic flanking sequences do not follow the GU-AG rule, noncanonical splicing removes these rarer introns with different splice site sequences using the minor spliceosome.[8] The same U5 snRNP is found in the minor spliceosome, in addition to the unique yet functionally similar U11, U12, U4atac, and U6atac. Furthermore, there are splicing mechanisms, including tRNA splicing and self-splicing, that function without use of the spliceosomal machinery. tRNA intron excision and exon ligation are catalyzed by protein-only complexes. tRNA introns typically interrupt the anticodon loop and must be removed so that the mature tRNA can properly function in protein translation.

Splicing is central to the output of a diverse transcriptome and then proteome. Alternative splicing (AS) can enhance the versatility and diversity of a single gene. By alternatively excising different introns along with the intervening exons, a wide range of unique transcripts and proteins of differing sizes can be generated. These alternatives, termed *isoforms*, come from one gene that generates a variety of mRNAs with varying exon composition. AS is widespread in complex

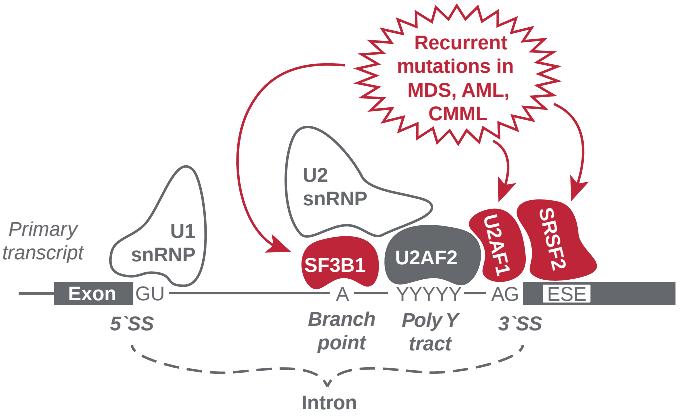

Figure 4.3 DESCRIPTION OF THE CANONICAL SPLICING JUNCTION, HIGHLIGHTING SPLICING FACTORS RECURRENTLY MUTATED IN HEMATOLOGIC MALIGNANCIES. Recognition of splicing sites is mediated by small conserved motifs: a GU dinucleotide at the beginning of the intron and an AG dinucleotide at the end, preceded by a polypyrimidine tract and a branch point A. Exons also contain functional sequences that promote splicing. All these motifs are bound by splicing factors that mediate the splicing process. Splicing factors highlighted in red are associated with hematologic malignancies. *3′SS*, 3′ splice site; *5′SS*, 5′ splice site; *AML*, acute myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *ESE*, exonic splicing enhancer; *MDSs*, myelodysplastic syndromes; *poly Y tract*, poly-pyrimidine tract; *snRNP*, small nuclear ribonucleoprotein.

multicellular organisms: the average human gene has seven different isoforms, and the number of known isoforms is rapidly increasing thanks to technologies such as long-read next-generation sequencing. AS is common and essential for the proper function of almost all hematopoietic cells. For example, B cells can produce both immunoglobulin M (IgM) and IgD at the same developmental stage using AS. Erythrocytes use AS to produce differing isoforms of cytoskeletal proteins. However, AS does not always give beneficial results.

One of the best examples of inappropriate splicing leading to hematologic disease is β-thalassemia, where several mutations that occur in the GU-AG splicing signals result in aberrant β-globin mRNAs. Abnormal splicing can also lead to AML, MDSs, and other hematologic disorders. Translocated in liposarcoma (TLS) is a protein that recruits splicing complexes to mRNAs and is involved in the TLS-ETS transcription factor ERG fusion oncogene in t(16;21) in AML. This fusion of TLS with the transcription factor ERG alters the splicing profile of immature myeloid cells, blocking the expression of genes required for proper differentiation. Trans-splicing is a form of splicing that joins two exons that are not within the same mRNA transcript. Some trans-splicing events occur when the intron splice sites are not filled by spliceosomes. Trans-splicing can lead to mRNAs displaying exon repetitions or chimeric fusion RNAs, which can mimic the presence of a chromosomal translocation in normal cells. For example, specific chimeric fusion mRNAs seen in acute leukemias, such as MLL-AF4, BCR-ABL, TEL-AML1, AML1-ETO, PML-RAR, NPM-ALK, and ATIC-ALK, have been found in blood cells of healthy individuals with normal chromosome karyotype. Interestingly, these individuals generally do not develop leukemia. In addition, in patients with chronic myelogenous leukemia (CML) resistance to tyrosine kinase inhibitor therapy has been linked to AS of the BCR-ABL transcript.

Splicing mutations in genes can occur *in cis* within the RNA itself as is the case for the aforementioned β-thalassemia, or *in trans* such as mutations in splicing factors or members of the spliceosome. Recurring mutations in several factors of the spliceosome result in MDSs and other hematologic malignancies (see Fig. 4.3).[9] Mutations in the splicing factor 3b, subunit 1 (SF3B1) have been observed in 68% to 75% and 81% of refractory anemia with ring sideroblasts (RARS) and RARS with thrombocytosis (T) patients, respectively, and result in alternative choice of the branchpoint site within the intron. Mutations in the U2 small nuclear RNA auxiliary factor I (U2AF1) and the serine/arginine-rich splicing factor 2 (SRSF2) result in sequence-specific splicing aberrations. U2AF1, a subunit of the U2AF heterodimer that also contains the polypyrimidine tract binding subunit U2AF2, carries distinct point mutations in its two zinc-fingers that contact the AG dinucleotide in the 3′ splice site. Mutations of U2AF1 S34 or Q157 residues create de novo 3′ splice site contacts that alter RNA splicing and result in preferential exon inclusion or exclusion, depending on the −3 or +1 nucleotide sequence at the 3′ splice site, respectively.[10] Mutations in U2AF1 are associated with a number of myeloid malignancies and occur in 8.7% to 11.6% of de novo cases of MDS. U2AF1-mutant MDS/AML cells exhibit enhanced stress granule response, pointing to a novel role for biomolecular condensates in adaptive oncogenic strategies.[10] SRSF2 is a member of the serine/arginine-rich pre-mRNA splicing factors. SRSF2 recognizes so-called splicing enhancer sequences (ESE) within exons (see Fig. 4.3), with a 5′-SSNG-3′ consensus motif where S = C/G and N = C/G/T/U. Mutations of P95 in the RNA-binding domain of SRSF2 alter RNA binding and splicing, reflected in higher affinity for 5′-CCNG-3′ than 5′-GGNG-3′ containing exons and resulting in preferential inclusion of alternative exons containing CCNG-rich motifs and exclusion of exons containing GGNG-rich motifs.[11,12] Mutations in the SRSF2 gene are associated with MDS and related diseases, particularly CMML, with SRSF2 mutations reported in up to 47% of patients. Recent studies have identified numerous critical targets aberrantly spliced, such as the member of the PRC2 complex EZH2, involved in epigenetic regulation.[12] In addition, it has been found that splicing factor mutations result in enhanced formation of DNA:RNA hybrids, so called *R-loops*, that induce DNA damage that promises to be exploitable in the treatment of these diseases.[13,14]

NUCLEAR EXPORT OF RNA

The nuclear envelope (NE) serves as a major regulator of gene expression, by controlling the movement of mature RNA from the nucleus to the cytoplasm for translation. The NE is made up of a double membrane. The outer nuclear membrane is continuous with the ER and has a composition distinct from that of the inner membrane. Nuclear pore complexes (NPCs) inserted within the NE regulate the transport of molecules in and out of the nucleus.[15] Ions, small metabolites, and proteins smaller than 40 kDa passively diffuse across NPC channels. However, larger proteins and mRNAs are transported through NPCs via energy-dependent (guanosine triphosphate [GTP]) and signal-mediated processes that require chaperoning transport proteins. Approximately 3000 NPCs perforate the NE in animal cells. NPCs are approximately 120 nm in external diameter and composed of three major parts: (1) a central core containing a 10-nm channel, (2) a nuclear basket that can dilate in response to large cargoes, and (3) flexible fibrils that extend from the central core into the cytoplasm. NPCs contain approximately 50 different proteins (nucleoporins), arranged in a complex cylindrical structure with an octagonal symmetry.[16] Nucleoporins constitute the scaffold of the NPC and are arranged in rings. In the inner ring, nucleoporins containing repeats of two hydrophobic amino acids, phenylalanine and glycine (FG-repeats), are essential for the movement of the cargo-carrier complexes and for creating a selectivity barrier against the diffusion of nonnuclear proteins. The FG-nucleoporin filaments protrude toward the inner core of the NPC and the weak hydrophobic interactions between the FG-repeats and the cargo-carrier complexes mediate the passage of molecules.

One nucleoporin, Nup98, is involved in numerous translocations and resulting fusion proteins that cause MDS and leukemia. The N-terminal (Nt) domain that contains the FG-repeats is fused to more than 28 partners in MDS and AML and has shown leukemogenicity in cell lines and mouse models. Interestingly, it is likely Nup98's transcriptional activation function rather than its role in nuclear pore formation that is critical in the function of these fusion proteins.[17]

Naked RNA cannot be exported through NPC channels. Rather, RNA export from the nucleus requires that newly synthesized RNAs undergo the previously described processing steps: 5′ capping, splicing, and 3′ polyadenylation. RNA-binding proteins, such as NXF1 that mediates the export of most mRNAs or XPO1, are required to fold and shuttle the modified RNA through NPCs. The eukaryotic translation initiation factor 4E (eIF4E) enhances nuclear export of a subset of RNA transcripts and is critical for proper granulocyte differentiation. Overexpression of eIF4E impedes myeloid maturation and can result in AML.[18] The cellular RNA export machinery is coopted by gammaretroviruses for the export of viral transcripts, such as binding of murine leukemia virus transcripts by the host cell's NXF1.

RNA HETEROGENEITY

The transcriptome of a cell is represented by a myriad of different RNA molecules with and without protein-coding capacities. Before recognition of the versatility of RNA, DNA was considered the sole conveyor of information while RNA was thought to solely function as an intermediate in protein synthesis (mRNA) or as effector molecules (tRNA, rRNA, snRNA). In the past couple of decades, RNA research has shed light on the pliability of RNA and its many regulatory functions in gene expression (Fig. 4.4). Several classes of noncoding RNAs (ncRNAs) such as *micro*RNAs (miRNAs), *piwi-interacting* RNAs (piRNAs), and *long noncoding* RNAs (lncRNAs) have been identified and associated with regulatory functions and diseases.[19] According to current genome annotations, the number of human ncRNAs is much higher than the number of protein-coding genes. The RNA landscape is further enriched by the presence of retrotransposons, a broad class of transposable elements, or "jumping genes," that duplicate through RNA intermediates that are reverse transcribed and inserted at new genomic locations. Due to their "copy and paste" mechanism, retrotransposons amplify in number quickly, composing 40% of the entire human genome.

LncRNAs are defined by their length, greater than 200 nucleotides (nt). They have gene regulatory roles in the nucleus or function in the cytoplasm via epigenetic, transcriptional, posttranscriptional, translational, and protein location effects. With almost 18,000 genes in the human genome, lncRNAs are apparently the most numerous and functionally diverse class of ncRNAs. Depending on their genomic location, they can be further divided in antisense (asRNAs), overlapping protein coding genes, or intergenic (lincRNAs) (see Fig. 4.4). Several lncRNAs undergo maturation processes such as capping, splicing, and polyadenylation. Despite their designation as ncRNAs, a considerable number of these transcripts tend to contain short open reading frames (sORFs) and bind with ribosomes, suggesting that the coding potential of lncRNAs has been vastly underestimated. Although the function of most lncRNAs is still unknown, multiple lincRNAs such as MALAT1, NEAT1, or XIST have already been implicated in human diseases such as cancer. An inherited form of α-thalassemia is caused by the translocation of an antisense lncRNA near the α-globin gene, resulting in the epigenetic silencing of the HBA2 gene and causing the disease.

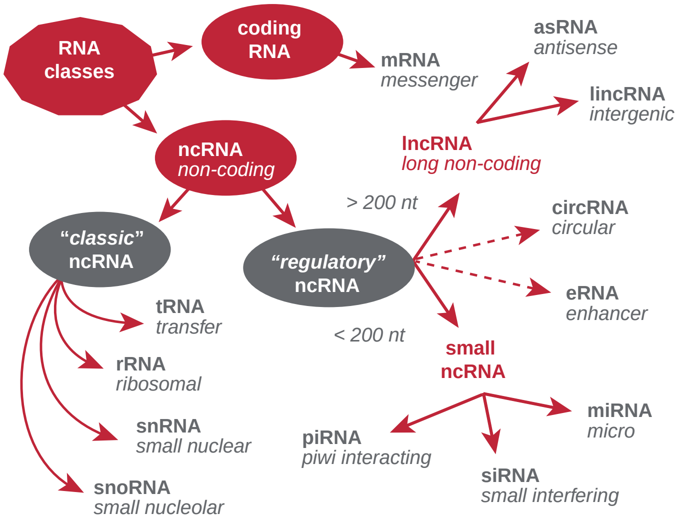

Figure 4.4 HIERARCHY OF RNA CLASSES DEFINED BY FUNCTION, BIOGENESIS, AND SIZE. The human genome contains more noncoding RNAs than messenger RNAs. Noncoding RNAs perform multiple functions, essential for both gene expression and its regulation.

Short ncRNAs, with a length less than 200 nucleotides, account for approximately 8500 genes in the human genome. They include well-known RNA classes such as tRNAs and rRNAs, essential for translation and described below in the section Protein Synthesis. snRNAs are associated with specific proteins in snRNPs and part of the spliceosomal complexes described in the section Regulation of RNA Processing: Capping, Splicing and Polyadenylation. Small nucleolar RNAs (snoRNAs) are a class of small RNA molecules that primarily guide chemical modifications of other RNAs, mainly rRNAs, tRNAs, and snRNAs.

More recently discovered classes of short RNAs include miRNAs, siRNAs, and piRNAs. The role of miRNAs and siRNAs are described in detail later (section RNA Interference). piRNAs are approximately 26- to 31-nt-long transcripts and function in suppression of transposable elements and maintenance of germline integrity.

Among emerging classes of RNAs, *circular RNAs* (circRNAs) are primarily produced via backsplicing of the 3′ end to the 5′ end of exons within the same transcript of a coding gene, giving these RNAs the circular shape. Compared with linear RNA, circRNAs form a covalently closed circular continuous loop and are highly conserved, stable, and tissue specific. CircRNAs can result in alternative protein isoforms and function as decoys for miRNAs and RNA-binding proteins, thereby regulating RNA stability and translation.

Enhancer RNAs (eRNAs) are generally relatively short ncRNAs transcribed from the genomic DNA at enhancer regions and represent a diverse class of molecules. They were originally described as nonpolyadenylated, bidirectionally transcribed RNA transcripts (<2000 nt) that originate from active enhancers. Subsequently some eRNAs were shown to be longer (>4000 nt), polyadenylated, and unidirectionally transcribed from higher-activity enhancers. eRNAs can regulate transcription in *cis* and in *trans*. Studies to identify their specific functions and mechanisms of action are ongoing.

ncRNAs, that once were mostly considered "junk" because they were diverging from the "central dogma," are proving to be an increasingly important part of our genome, an intricate layer of signals that control gene expression in physiology and disease.

REGULATION OF RNA METABOLISM: STABILITY AND LOCALIZATION

In mammalian cells, RNA lifetimes range from several minutes to days and represent a tightly regulated balance of transcription (detailed earlier) and degradation. The limited lifetime of mRNAs enables a cell to alter protein synthesis in response to its changing needs. The stability of mRNA is regulated by several mechanisms, including via sequences within the *untranslated regions* (UTRs) of mRNA, via nonsense-mediated decay (NMD) and via RNA modifications. Within the mature mRNA, the coding sequence (CDS) contains the sequence that is translated into protein, from the start codon to the stop codon. UTRs before the start codon (5′UTR) and after the stop codon (3′UTR) are not translated but govern mRNA half-life, localization, and translational efficiency. In human mRNAs, UTR regions are on average as long as the CDS (5′UTR: 236 nt, CDS:1121 nt, 3′UTR: 1047 nt). Both proteins and small RNA species can bind to either the 5′ or 3′ UTRs to regulate translation or influence survival of the transcript. NMD is a surveillance pathway present in all eukaryotes whose main function is to reduce errors in gene expression by eliminating mRNA transcripts that contain premature termination codons (PTCs). In addition to quality control, NMD can also serve to regulate expression in conjunction with AS. More recently, RNA modifications have emerged as a powerful mechanism of regulation of RNA stability and possibly translation. miRNAs, small RNA molecules that bind to complementary sequences on target mRNA transcripts, provide additional regulation of mRNA stability and translation.

Regulation of RNA Stability by 5' and 3' UTR Sequences and Structures

UTR sequence regulation of mRNA survival is essential for proper hematopoietic differentiation. The best example of this is globin synthesis, where the mRNA is very stable because of its UTR sequences. This long half-life meets the needs of reticulocytes to synthesize globin for up to 2 days after terminally mature erythroblasts lose the nucleus and the ability to make new mRNA.

Some of the elements contained in UTRs form a characteristic secondary structure that alters the survival of the mRNA transcript, exemplified by the prothrombin 3′ UTR. This mRNA is constitutively polyadenylated at seven or more alternative positions, and the 3′ UTR folds into at least two distinct stem-loop conformations.[20] These alternate structures expose a consensus binding site for trans-acting factors, such as heterogeneous nuclear ribonucleoprotein 1 (hnRNP-I), polypyrimidine tract-binding protein-1 (PTB-1), and nucleolin, with translational regulatory properties. Another type of 3′ UTR regulatory sequence involves selenocysteine insertion sequence (SECIS) elements. These represent another stem-loop RNA structure found in mRNA transcripts and serve as protein-binding sites on UTR segments that direct the ribosome to translate the codon UGA as selenocysteine rather than as a stop codon. An example of this regulation can be found in selenoprotein P in plasma. Bacteria contain another class of these mRNA elements, the *riboswitches*, that directly bind the small molecules that their mRNAs encode thereby directly regulating their own activity in response to the concentrations of their effector molecules. Bacterial riboswitches are relevant to hematopoiesis since the mRNAs for several enzymes in the cobalamine pathway in intestinal bacteria have riboswitches; these bind adenosylcobalamine that in turn regulates the survival and translation of these mRNAs and finetunes cobalamine synthesis.[21] Riboswitches are promising new drug targets, for now against bacteria, exemplifying the opportunities in RNA therapeutics.

Another class of UTR functional sequences affecting the stability of the mRNA is the *AU-rich element* (ARE). AREs are stretches of mRNA consisting mostly of adenine and uracil nucleotides. These sequences destabilize their transcripts through the action of riboendonucleases that stimulate poly(A) tail removal. Loss of the poly(A) tail is thought to promote mRNA degradation by facilitating attack by both the exosome complex and the decapping complex. Rapid mRNA degradation via AREs is a critical mechanism for preventing the overproduction of potent cytokines such as tumor necrosis factor (TNF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). AREs also regulate the synthesis of mRNA for proto-oncogenic transcription factors such as c-Jun and c-Fos. The AU elements in the mRNA of these genes mediate destruction of their transcripts in quiescent cells, preventing inappropriate cell proliferation that would occur if Fos/Jun were still active.

Besides transcript stability, the efficiency of translation can be regulated by cellular factors that bind mRNA in a sequence-specific manner. Iron metabolism is an excellent example of how cells coordinate uptake and sequestration of an essential metabolite in response to availability. Transferrin is a plasma protein that carries iron. Receptors for transferrin (TfR) are expressed on cells requiring iron for maturation, such as erythroid progenitor cells. They mediate internalization of transferrin loaded with iron into the cytoplasm through receptor-mediated endocytosis. When a cell becomes iron deficient, iron-responsive element–binding proteins (IRE-BPs) can bind to iron-responsive elements (IREs) in the UTR of transferrin receptor (TfR) mRNA (Fig. 4.5). UTR binding leads to stabilization of the TfR mRNA transcript and in increased protein expression. However, when a cell has sufficient iron, as iron binds to more and more IRE-BPs, they change shape and unbind the TfR mRNA. The TfR mRNA becomes unstable and is rapidly degraded (see Fig. 4.5). Therefore, in that situation, TfR receptor expression is low and the fewer receptors import lessiron.

Nonsense-Mediated Decay

Eukaryotic mRNA messages are subject to surveillance for accuracy by a mechanism termed *nonsense-mediated decay* (NMD). The NMD complex surveys the transcript for the presence of PTCs (nonsense codons) in the message. These PTCs can arise via either a mutation in the gene from a sense codon to a termination codon (seen in thalassemias), incomplete splicing due to mutations in DNA, transcription errors, or leaky scanning by the ribosome, causing frame shifts. Detection of a PTC by NMD triggers mRNA degradation by 5′ decapping, 3′ poly(A) tail removal, or endonucleolytic cleavage. NMD does not only function to safeguard the cell against transcripts with PTCs generated in error, but it also serves gene expression regulation in a negative feedback loop, in which, for example, RNA-binding proteins bind their own pre-mRNAs and cause AS to introduce a PTC. Prominent examples in hematopoiesis that use NMD for regulation of transcript abundance include erythropoiesis[22] and granulopoiesis,[23] where AS coupled to NMD regulates transcript abundance at the posttranscriptional level. Examples of NMD in disease include splicing factor mutants, and specifically SRSF2 mutant MDS, in which preferential inclusion of an alternatively spliced exon, called *poison exon* for its deleterious effects on the transcript, results in a PTC and NMD of the EZH2 transcript.[12]

RNA Modifications: The Epitranscriptome

The past half century has witnessed numerous discoveries in the mechanisms regulating gene expression. Direct modifications of RNAs, abundant in tRNAs, rRNAs, and mRNAs, serve to regulate the function of the RNA molecules themselves. Posttranscriptional RNA modifications encompass more than 160 different chemical variations on the four canonical ribonucleotides, with diverse impacts on transcript fate and function. mRNAs can be modified by more than 10 different chemical marks, including m^{6}A, N^6,2′-O-dimethyladenosine (m^{6}A$_m$), 5-methylcytosine (m^{5}C),

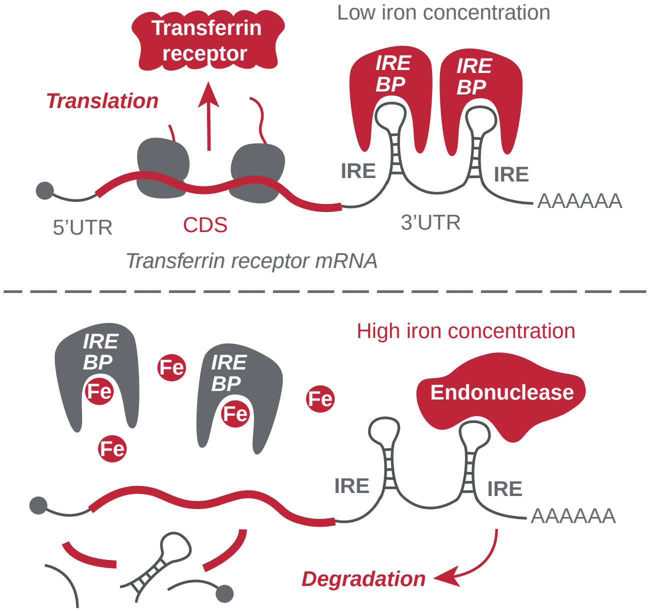

Figure 4.5 CONTROL OF TRANSFERRIN RECEPTOR EXPRESSION BY RNA STABILITY. The transferrin receptor messenger RNA *(mRNA)* has five RNA iron-responsive elements *(IRE)* in the 3′ untranslated region *(3′ UTR)*. Upper panel: when the iron concentration is low, the IRE-binding proteins *(IRE-BPs)* bind to the IRE elements and stabilize the mRNA, reading to increased protein expression. When the iron concentration is high *(Fe)*, IRE-BPs are inactive and the transferrin receptor transcript is susceptible to degradation by endonucleases, leading to decreased protein expression. *CDS*, Coding sequence.

and rarely N^1-methyladenosine (m^{1}A). The modified nucleotide N^6-methyladenosine (m^{6}A) is the most prevalent mRNA internal modification in mammalian cells and is placed on average on one to three adenosines per mRNA transcript; the m^{6}A modification was first identified as an abundant internal mRNA modification as early as the mid-1970s, and its principal methyltransferase, METTL3, was discovered shortly thereafter (Fig. 4.6). However, the field of "RNA epigenetics" or "epitranscriptomics" was not unlocked until publication of the first transcriptome-wide m^{6}A maps, derived by coupling RNA immunoprecipitation with an m^{6}A-specific antibody with next-generation sequencing (MeRIP-seq). The m^{6}A mark is placed within the DRACH RNA consensus motif (where D = G, A, or U; R = G or A; and H = C, A, or U) by the methyltransferase complex with the METTL3-METTL14 heterodimer at the core (m^{6}A "writers"). m^{6}A modification can be removed by m^{6}A "erasers" (ALKBH5) (see Fig. 4.6). The function of m^{6}A is executed by m^{6}A "readers" that bind to m^{6}A directly (YTH domain-containing proteins, eIF3, IGF2BPs) or indirectly (HNRNPA2B1). The m^{6}A RNA modification plays key roles in RNA metabolism, in particular RNA stability (reviewed in Zaccara et al.[24] and Shi et al.[25]). Deletion of the m^{6}A methyltransferase METTL3 or its binding partner METTL14 in HSCs results in bone marrow failure in adult as well as fetal hematopoiesis. One of the mechanisms at the basis of hematopoietic failure is loss of MYC, whose transcript is highly m^{6}A modified[26,27]; in addition, loss of m^{6}A results in aberrant endogenous dsRNA formation and activation of a deleterious innate immune response.[28] Reexpression of MYC or suppression of the innate immune response in *Mettl3*-deleted HSPCs partially rescues hematopoiesis. Perturbation of m^{6}A RNA writers, readers, and erasers (see Fig. 4.6) further supports the critical role of the m^{6}A modification in hematopoiesis. In addition, writers, erasers, and readers are emerging as possible targets in the treatment of leukemia and development and studies of small molecule inhibitors are in their early stages[29] (reviewed in Vasic et al.[30]).

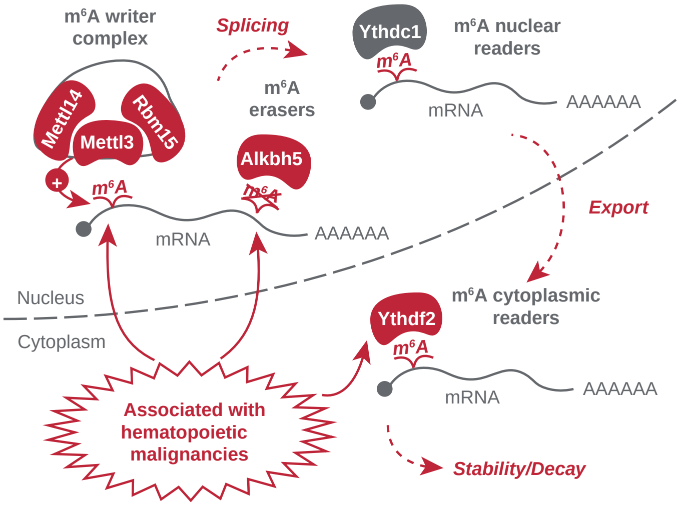

Figure 4.6 OVERVIEW OF M^{6}A MODIFICATION AND ITS RELEVANCE IN HEMATOLOGY. The m^{6}A writer complex, including the core methyltransferase METTL3 and its adaptors, adds m^{6}A to mRNAs prevalently during transcription. The m^{6}A erasers are largely localized in the nucleus as well. m^{6}A deposition can be reversed in the nucleus by the m^{6}A eraser ALKBH5. m^{6}A can be recognized by specific nuclear reader proteins such as YTHDC1, affecting nuclear processes such as splicing or export. In the cytoplasm, m^{6}A can be bound by specific reader proteins, such as YTHDF2, that affect the stability and possibly the localization or translation of the mRNA. m^{6}A factors highlighted in red are associated with hematologic malignancies.

RNA Interference

Another powerful mechanism of regulation of gene expression at the RNA level is RNA interference (RNAi), mediated by *miRNAs*; miRNAs are small RNAs (21 to 24 nucleotides in length) that bind to complementary sequences on target mRNA transcripts, prevalently in the 3′UTR. This binding results in transcript degradation and inhibition of translation and consequent silencing of gene expression (i.e., lack of protein output). There are now more than 2000 miRNA molecules coded in the human genome that regulate approximately one third of human genes. Each miRNA has the potential to target hundreds of genes. Conversely, an estimated 60% of all mRNAs have one or more sequences that are predicted to interact with miRNAs. RNAi has been very useful in the laboratory, allowing investigators to repress the expression of specific genes to study artificially induced phenotypes. In these studies, siRNAs are synthesized to bind to homologous sequences within specific mRNAs. The siRNAs and respective nontargeting controls are then transfected into cells, where they mediate destruction of their target mRNA through endogenous ribonucleases. Repression of gene expression in this manner has become known as "gene knockdown" and continues to be widely used to define the function of genes, by assessing what function the cell lacks in the absence of the expression of the target gene. The siRNA-mediated knockdown strategy is now being partially replaced by so-called CRISPR/Cas9-mediated gene deletion, which is covered in other chapters of this book.

To perform their function, both miRNAs and siRNAs are bound by a multiprotein complex called the RNA-induced silencing complex (RISC). Members of the Ago family of proteins are central to RISC function. Argonautes contain two conserved RNA-binding domains: a PAZ domain that can bind the single-stranded 3′ end of the mature miRNA and a PIWI domain that functions to interact with the 5′ end of the guide strand. Ago proteins bind the mature miRNA, orient it for interaction with a target mRNA, and may also directly cleave target transcripts (Ago2). The specificity of miRNA and siRNA interactions with their target mRNAs mediates how they regulate gene expression. For example, the specificity of miRNA targeting is ruled by Watson-Crick complementarities between positions 2 to 7 at the 5′ end of the miRNA, the so-called seed sequence, and the 3′ UTR of their target mRNAs.

Two models have been proposed to explain how miRNAs and siRNAs interfere with the expression of target genes: directed degradation of the target mRNA, performed as aforementioned by the RISC complex, and interference with the translation of a target mRNA (Fig. 4.7). In the case of *directed mRNA degradation*, the proposed model involves miRNA-mRNA binding and recruitment of RISC, which ultimately leads to degradation of the target mRNA. In the *interference model* the interaction of miRNA, RISC, and mRNA blocks the ribosomal machinery along the mRNA transcript, preventing translation. In reality, both models could contribute to gene expression downregulation. Most of the proteins necessary for miRNA-mediated gene silencing are located in cytoplasmic organelles, so called *P-bodies*, that are formed via phase separation. The specific circumstance of P-body involvement in miRNA-mediated RNA degradation is still an area of active research.

Various diseases, including many cancers, exhibit aberrant expression of miRNAs.[31] Regulation of the Tet2 mRNA by miR-22, dysregulated in MDSs and AML, is shown in Fig. 4.7. Another example is the *miR-15a/miR-16-1* cluster (located on chromosome 13q) chronic lymphocytic leukemia (CLL). When this cluster is deleted in B lymphocytes, there are higher levels of antiapoptotic proteins such as BCL2 and MCL1 but also higher levels of the tumor suppressor protein TP53. High levels of antiapoptosis yet with an intact TP53 tumor suppressor pathway could explain why 13q deletions in CLL are associated with an indolent form of the disease.[32] Several miRNAs have been identified that regulate hematopoiesis and in particular lineage choice and differentiation. One such miRNA is *miR-155* that retains HSCs and progenitor cells in an undifferentiated state and is downregulated with lineage differentiation. *MiR-155* is regulated by the homeobox gene *HOXA9*.

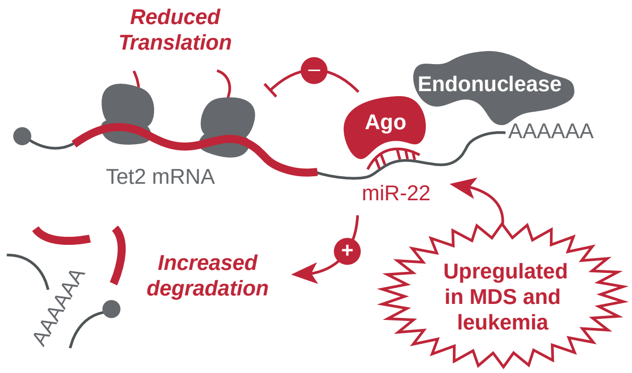

Figure 4.7 RNA INTERFERENCE AND THE CONTROL OF TET2 GENE EXPRESSION. The fully processed miR-22 microRNA associates with Ago proteins and binds target messenger RNAs (mRNAs), such as the 3′ untranslated region of Tet2, by sequence complementarity. RNA interference results in decreased translation and increased degradation of the target mRNA. The expression of several miRNAs, such as miR-22, is altered in hematologic malignancies, leading to dysregulation of all their targets. *MDSs*, Myelodysplastic syndromes.

RNA Granules and Membraneless Organelles

In the nucleus and in the cytoplasm, RNA availability and fate are additionally controlled by their localization in so-called RNA granules, liquid droplets, or membraneless organelles; within the same organelles, RNA may exert regulatory control on the function and availability of proteins and RNA-protein complexes.[33] Within the cell such organelles exist in the nucleus, such as nucleoli, Cajal bodies, nuclear speckles, and paraspeckles. In the cytoplasm, they exist in the form of processing (P) bodies, stress granules, and germ granules (Table 4.1). Liquid droplet organelles are formed by LLPS similar to the separation of oil and vinegar in vinaigrette. They function as organizational tools by concentrating cellular components in membraneless structures that allow rapid exchange of their components unhindered by membrane barriers. Their "fluidity," for most components' residence times, ranges from seconds to tens of seconds and allows for dynamic finetuning of biochemical reactions and rapid response to cellular stress. In general, liquid droplet organelles are made up of RNA and RNA-binding proteins. As an example, Cajal bodies in the nucleus form on active snRNA loci and are the site of snRNA processing and snRNP assembly and surveillance. Nucleoli regulate rRNA synthesis and are known to capture and detain proteins via lncRNA binding. Nuclear speckles and paraspeckles form on the two long ncRNAs MALAT1 and NEAT1, respectively, and contain mRNAs and their RNA-binding proteins. Nuclear speckles are the sites of RNA splicing. Paraspeckles sequester proteins and RNAs in response to cellular stress. Stress granules and P-bodies in the cytoplasm regulate RNA stability and protein translation. RNA is sequestered in stress granules in response to stress signals, hypothesized to regulate translation, RNA stability, and cell survival; in P-bodies, translation is stalled and transcripts are targeted for degradation by exonucleases.

TABLE 4.1 **RNA Granules**

Name	Localization	Composition	Function
P-bodies	Cytoplasm	RNA & protein	mRNA decapping, degradation, nonsense mediated decay, storage, translational repression by miRNAs
Stress granules	Cytoplasm	RNA & protein	Storage of RNAs and translation components under stress
Germ granules	Cytoplasm	RNA & protein	Regulation of proteins and RNAs required for germ cell development
Nucleoli	Nucleus	DNA, RNA, & protein	Ribosome biogenesis
Cajal bodies	Nucleus	RNA & protein	snRNP biogenesis
Nuclear speckles	Nucleus	DNA, RNA, & protein	Splicing regulation
Paraspeckles	Nucleus	RNA & protein	Transcription regulation, retention of edited RNAs under stress, mediated by lncRNAs (NEAT1)

lncRNA, Long noncoding RNA; *miRNA*, microRNA; *mRNA*, messenger RNA; *snRNP*, small nuclear ribonucleoproteins.

The study of LLPS and the function of liquid droplet organelles in vivo and their role in physiologic responses and disease are an ongoing subject of intense studies.[34] Aberrant phase transitions from a liquid state to a more aggregated state have been recognized as the causal mechanism in neurodegenerative disorders (e.g. via mutations in the RNA-binding proteins usually part of stress granules that render the proteins more likely to aggregate) and cancers.

PROTEIN SYNTHESIS

Translation is a biologic process performed by ribosomes, which use an mRNA as template for protein synthesis. Translation is a highly conserved, energy-consuming process. For this reason, it is tightly controlled.[35] In cells, multiple ribosomes can bind the same mRNA, forming complex structures, called polyribosomes, or polysomes. They mediate the formation of a polypeptide chain using the noncoding tRNA bound to amino acids to catalyze the synthesis of proteins. Amino acids, each with unique physicochemical properties (see Table 4.2 for single letter designations) are joined to tRNAs by amino-acyl-tRNA synthetases. The amino-acylated tRNAs enter the ribosome, which catalyzes the formation of peptide bonds by the condensation of the α-carboxyl group (COOH) of one amino acid with the α-amino group (NH_2) of another. The free NH_2 and COOH groups of the terminal amino acids define the amino- or Nt and the carboxyl- or C-terminal end of the resulting polypeptide chain, respectively. In many cases multiple polypeptide chains assemble into a functional protein complex. For example, hemoglobin is formed by four polypeptide chains, two α-globin and two β-globin chains that assemble with heme, an iron-containing prosthetic group, to yield the functional protein that delivers molecular oxygen to all cells and tissues.

The Process of Translation

The *ribosome* is a large, macromolecular machine that orchestrates the entire process of protein synthesis. Each human ribosome comprises four rRNAs and approximately 80 proteins, called ribosomal proteins (RPs), assembling into a 4.5-MDa structure. The ribosome is formed by two subunits; the large 60 S (S stands for Svedberg unit and refers to the sedimentation coefficient) and the small 40 S subunit join and constitute the 80 S ribosome in eukaryotic cells. rRNAs are the catalytic elements, and RPs are classically considered structural "scaffolding" units. The process of translation of an mRNA is typically divided into four phases: initiation, elongation, termination, and ribosome recycling. During the initiation phase the 40 S subunit binds to the 5′ cap of the mRNA and scans the mRNA toward its 3′-end searching for the translation start codon. The start codon is a trinucleotide sequence, usually an AUG, located within a Kozak consensus

TABLE 4.2 Examples of Sorting Signals

Organelle	Signal Location[a]	Example
Posttranslational Uptake		
Nucleus	Internal	SP**KKKRK**V*E* (import; NLS of SV40 large T antigen)
		KR-spacer **(**PAATKKAGQ)**-KKKK** (import; bipartite NLS of nucleoplasmin)

sequence (A/GNNAUGG), which is the optimal nucleotide context for translation initiation. The initiator tRNA specific for methionine, called the initiator $tRNA_i^{Met}$, binds the 40 S subunit and helps to recruit the larger 60 S subunit once the AUG is found. Next, the mRNA sequence is read in triplets by additional aminoacyl-tRNAs which mediate the elongation of the polypeptide chain (elongation phase). Translation is terminated as soon as the ribosomes reach a stop codon (termination phase). The polypeptide is then released, and ribosomal subunits detach from the mRNAs and are used for a new cycle of translation (ribosome recycling phase). Typically, multiple ribosomes are simultaneously engaged in translating a single mRNA molecule forming a polyribosome, or polysome. The phases of protein synthesis are regulated by eukaryotic initiation, elongation, and termination (or release) factors, termed eIFs, eEFs, and eRFs, respectively. eIFs are members of the guanine nucleotide-binding proteins (G protein) superfamily that function as molecular switches and promote unidirectionality of cellular processes. eIF2a also functions as a key mediator of the *integrated stress response* (ISR) limiting translation initiation and protein synthesis in response to stress conditions, such as amino acid or glucose starvation and viral infection.

As an example, in reticulocytes, heme starvation inhibits the synthesis of α- and β-globin chains via regulation of eIF2. Activated protein kinase hemin-regulated inhibitor (HRI) phosphorylates the α subunit of eIF2; phosphorylated eIF2 sequesters the guanine-nucleotide exchange factor (GEF) eIF2B, limiting its availability for the exchange reaction of eIF2-GDP to eIF2-GTP, halting globin translation. Heme availability thus becomes the rate-limiting step and prevents toxic accumulation of globin chains in the absence of heme.

A second major control point of general protein synthesis is mediated by the eIF4F heterotrimeric protein complex that makes the mRNA accessible to binding by the 40 S ribosome subunit: its cap-binding protein eIF4E binds the mRNA cap, the ATP-dependent RNA helicase eIF4A unwinds structural elements in the 5′-end of mRNA, and eIF4G serves as scaffold protein in the complex. As the lowest abundance subunit, eIF4E represents the rate-limiting step in protein synthesis. In addition, inhibition of the cap-binding activity of eIF4E by eIF4E-binding proteins (eIF4EBPs) prevents assembly of the eIF4F complex.

Additional modes of regulation take advantage of the mRNA sequence itself. In the control of iron metabolism, IREs, hairpin structures formed in the UTRs of mRNAs, are bound by IRE-BPs. In iron-starved cells, IREs in the 3′UTR and 5′UTR of TfR and ferritin mRNAs, respectively, are bound by IRE-BPs that stabilize the TfR transcript while at the same time inhibiting translation initiation of ferritin (see Fig. 4.5). Conversely, when iron is abundant, IRE-BPs have a lower affinity to IREs, and as a result TfR mRNA is degraded whereas ferritin mRNA translation is stimulated. In this manner, cells can coordinately regulate iron uptake and iron sequestration in response to changes in iron availability.

Ribosome Disorders

Given the importance of translation in regulating protein expression in all fundamental physiologic processes, gene expression is largely controlled at the translational on top of the transcriptional level.[36] Translation is the most energy-consuming process in cells, and its dysregulation is implicated in an ever-increasing number of diseases. Evidence accrued over the past decades demonstrates that cancer[37] and neurodegenerative diseases[38,39] share defects in RNA processing or translation. Hematologic disorders are no exception.

Ribosomes have been put in the spotlight as putative direct players in finely tuning translation by acting as mRNA filters.[40] Recent papers suggest that ribosome composition is not fixed and uniform but rather heterogeneous and modulated at the level of RP composition[41] or rRNA variants[42,43] and further modified posttranslationally or posttranscriptionally.[44,45] This ribosome heterogeneity, known as "specialized ribosome" hypothesis, could exert a direct role in mRNA selection.[46] Moreover, ribosome-associated factors[45] have been shown to possibly control translation. In addition, the number of ribosomes can play a crucial role in controlling the subset of mRNAs undergoing translation,[47] thus shaping the cellular proteome.

Recent years have led to the discovery of an increasing number of germline and somatic mutations affecting translation at multiple levels. These defects include mutations in structural constituents of the ribosomes, such as RPs, or in translation-related ncRNAs such as tRNAs (Table 4.3). Interestingly, in very recent years, alterations in posttranscriptional modifications of rRNA have been observed as well as deregulation of the cellular ISR and the mTOR pathways (reviewed in Tahmasebi et al.[54]).

Classically, the best-known hematologic disorders associated with genetic mutations in genes encoding RPs or assembly factors required for ribosome biogenesis and function are called *ribosomopathies*. Ribosomopathies represent a range of disorders characterized by genetic abnormalities impacting on ribosome biogenesis and function. These defects cause specific clinical phenotypes and are well-known risk factors for myelodysplastic disorders and AML. Ribosomopathies can be divided into subgroups depending on where the mutation affects the ribosome.

Ribosomopathies caused by mutations in RPs most often have in common the development of bone marrow failure or anemia and/or craniofacial or other skeletal defects with an increased cancer risk later in life of the affected individual.

Commonly inherited mutations in as many as 18 diverse RP genes cause Diamond-Blackfan anemia (DBA) in children. The clinical features are erythroid hypoplasia in an otherwise normocellular marrow that manifests with a macrocytic anemia. Up to 50% of patients with DBA also have short stature, craniofacial defects, thumb abnormalities, and congenital heart malformations. Mutations in RPs (see Table 4.3) are identified in up to 50% of DBA patients and in general function in an autosomal dominant manner. Mutations in these genes lead to haploinsufficiency of the corresponding RPs which causes direct defects in proper ribobiogenesis and decrease in ribosome number. Interestingly, also mutations in GATA1, a transcription factor essential in erythropoiesis, cause DBA, and, as seen in DBA with RP defects, GATA1 mRNA is more sensitive to downregulation of RPs.[55,56]

Another remarkable example of hematologic disorders connected to mutations in an RP is the $5q^{-}$-syndrome, a subtype of MDS. Haploinsufficiency of RPS14, resulting from acquisition of an interstitial deletion on chromosome 5q,[57] causes a refractory anemia very similar to DBA.

Another inherited hematologic disorder indirectly connected to translation is the Schwachman-Diamond syndrome (SDS). This syndrome is characterized by impaired hematopoiesis and neutropenia, exocrine pancreas dysfunction, and bone defects. SDS is caused by mutation in the *SBDS* gene, which does not encode for an RP as in the case of DBA and 5-q syndrome but which has critical function in ribosome maturation.

In addition to mutations in RPs, defects in proper posttranscriptional modifications of rRNA exist. Examples include dyskeratosis congenital (DKC), an x-linked disorder, caused by mutations in dyskerin (DKC1) which mediates pseudouridylation of rRNA. In addition to this genetic disorder, defects in other types of posttranscriptional modifications of rRNA have been observed. Changes in the expression level of ncRNA involved in highly specific 2′O-methylations have been connected to B-cell lymphomas and self-renewal control of leukemia cells. Similarly, changes in expression levels of NAT10, involved in rRNA acetylation, were linked to AML (reviewed in Janin et al.[58]), further suggesting that finely tuned translational control plays a fundamental role in the hematologic pathophysiology.

In the past years, defects in tRNA processing and posttranscriptional modification have been observed both in genetic and somatic hematologic conditions. Cartilage hair hypoplasia (CHH) was first described in Amish families as a form of short-limbed dwarfism caused by skeletal dysplasia. The patients show immune dysfunction and an increased risk of acquiring non-Hodgkin lymphoma in adulthood. In addition, defects in uncommon modifications of tRNA, such as queuosine, have been found to be associated with carcinogenesis and leukemia.

Several RPs have extraribosomal functions important for cell proliferation and differentiation, DNA repair, apoptosis, and others resulting in defects independent of protein translation. Mutations affecting members of the ISR that senses cellular stresses and adapts gene expression to stress predominantly cause disorders of cells with high secretory demands, such as pancreatic cells or in neuronal cells. The mTOR pathway coordinates anabolic and catabolic processes in response to internal and external stimuli; rapamycin, an inhibitor of mTOR, inhibits translation initiation. Defects in the mTOR pathway predominantly result in neurologic disorders. Both activating and loss-of-function mutations in the class IA PI3K PIK3CD or its regulatory subunit PIK3R1 cause immunodeficiency.

All ribosomopathies connected to hematologic outcomes have increased cancer risk with development of MDSs or AML, or head and neck tumors in DKC and lymphomas and basal cell carcinomas in CHH.[59] Studies suggest that translational output of the misassembled, structurally distinct ribosomes may favor translation of growth-promoting, oncogenic proteins or translation-independent regulation of oncogenes, such as MYC. Changes in ribosome composition may result in "onco-ribosomes." In addition, ribosome defects may alter cellular protein and energy balance and create cellular stress conditions conducive to acquisition of secondary mutations. Elevated levels of reactive oxygen species (ROS) in ribosomopathies are associated with high oxidative stress and result in DNA damage and genomic instability and acquisition of cooperating mutations. Preventing the switch from hypoproliferation to hyperproliferation offers a chance to prevent cancer in patients affected by these disorders.

Despite the universal expression of ribosomal genes or ribosome-related genes and ribosomal assembly factors in all tissues, the clinical presentation is dictated by the function of the affected genes and tissue-specific reliance on affected pathways. It is clear that mutations in RP genes or other proteins involved in ribosome biogenesis are causing highly specific phenotypes in specific cell types and tissues. The question as to why changes in the ubiquitous expression of these proteins and ncRNAs as well as the global requirement for protein synthesis drive specific phenotypes remains to be fully answered.

Three models prevail to explain the phenotypic variability of ribosomopathies: (1) defects in ribosome biogenesis and function result in reduced effective *ribosome concentration* that leads to diminished translation of a subset of mRNAs, as recently proposed for DBA[60] in certain tissues that are most sensitive to changes in ribosomal function; (2) the composition of ribosomes varies, imparting *specialized ribosome* function to different cell types resulting in disruption of translation of a subset of mRNAs; (3) impaired ribosome biogenesis activates the tumor suppressor p53 pathway via accumulation of unassembled RPs that bind the E3 ubiquitin-protein ligase MDM2, suppress its activity, and stabilize p53, resulting in cell cycle arrest and apoptosis.[47]

PROTEIN SORTING

Most proteins are synthesized on free polysomes and remain in the cytosol, where they are further modified. These proteins, which should reside in the cytoplasm, include enzymes involved in many metabolic and signal transduction pathways, proteins required for mRNA translation or assembly of the cytoskeleton. Other proteins are targeted toward organelles while being translated on ribosomes and are imported cotranslationally. Other proteins are produced in the cytoplasm and transported posttranslationally from the cytosol into organelles, including the nucleus, mitochondrion, and peroxisome (Fig. 4.8). These protein-trafficking events are governed by sorting signals (i.e., short amino-acid sequences or three-dimensional patches of particular amino acids) and by cognate receptors (see some examples in Table 4.2). The first sorting decision occurs after approximately 30 amino acids of the nascent polypeptide are extruded from the ribosome. If the nascent polypeptide lacks a "signal sequence," the translation of the polypeptide is completed in the cytosol. The protein either remains in the cytosol or is posttranslationally translocated into an organelle. If the protein contains an amino-terminal signal sequence, it is imported cotranslationally into the ER. From the ER, proteins are trafficked to the Golgi compartment and lysosomes via the vesicle pathway.

Targeting of Nuclear Proteins

For a detailed description of the NPCs, refer to the previous section on Nuclear Export of RNA.

NPCs are capable of importing and exporting molecules or complexes, provided that the molecules have an exposed nuclear localization signal (NLS) or a nuclear export signal (NES). In Table 4.2, some of the best-known signals are listed. The NLSs are not cleaved off as occurs for other signals (see later) and thus can function repetitively. Candidates exposing signals for nuclear import (i.e., transcription factors, coactivators or corepressors, DNA repair enzymes, RPs and mRNA processing factors, etc.) or export (ribosomal subunits, mRNA-containing particles, tRNAs, etc.) are transported through the NPC in association with soluble carrier proteins, called karyopherins (also called importins, exportins, or transportins), which function as shuttling receptors for different protein cargos. Ran is a small Ras-like GTPase, belonging to the G protein superfamily, that controls both the docking of carrier proteins with their cargo and the directionality of transport through cycles of GTP binding and hydrolysis.

NF-κB, a nuclear factor for the transcriptional enhancer of the κ light chain in B lymphocytes and a key element of the stress response, is normally retained in the cytoplasm by interaction with IκB. The TNF-α–dependent phosphorylation of IκB releases NF-κB, thereby exposing an NLS and that allows NF-κB to migrate into the nucleus, where it activates transcription of its target genes. For the glucocorticoid receptor (GR), which is localized in the cytoplasm, binding to its ligand exposes an NLS recognized by an importin and allows translocation into the nucleus, where GR activates genes by binding to GR-responsive elements in their promoter regions. The karyopherin export factor XPO1 is overexpressed in a variety of cancer cell types, including multiple myeloma and leukemia. A small molecule inhibitor of XPO1 inhibits the export of leucine-rich NES-dependent proteins, including that of tumor suppressors, such as TP53, TP21, BRCA1/2, pRB, and FOXO, that detect DNA damage in the nucleus and limit cancer cell survival.[61]

Cotranslational Protein Translocation Into the Endoplasmic Reticulum

The ER is an extensive membranous network that is continuous with the outer nuclear membrane and is the site for the synthesis of the massive amounts of lipids and proteins used to build the plasma membrane and the membranes of most cellular organelles. The ER comprises three interconnected domains: rough ER, smooth ER, and ER exit sites. The rough ER, abundant in cells specialized in protein secretion, such as cells of exocrine glands or plasma cells, is studded with bound ribosomes that are actively synthesizing proteins. The smooth ER lacks ribosomes, is not very abundant in most cells (except hepatocytes), and is thought to be the site of lipid biosynthesis and of cytochrome P450–mediated detoxification reactions. ER exit sites are specialized areas of the ER membrane where transport cargo is packaged into transport vesicles en route to the Golgi apparatus.

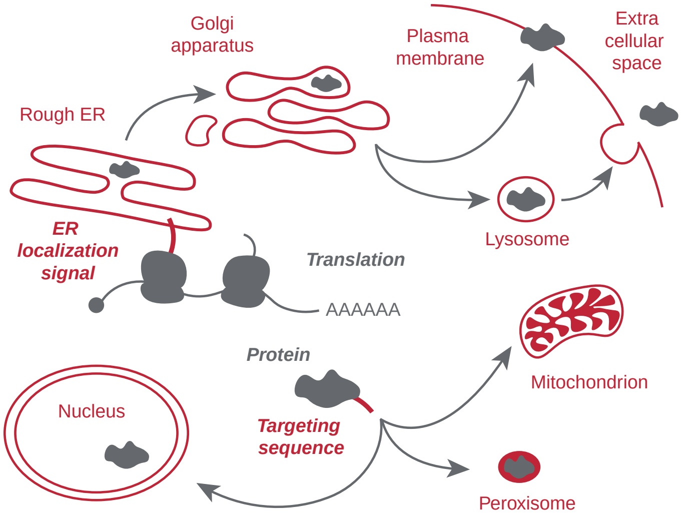

Figure 4.8 FOLLOWING TRANSLATION, PROTEINS ARE SORTED TO DIFFERENT DESTINATIONS. Depending on the presence of targeting sequences, proteins can be targeted to the nucleus, mitochondrion, or peroxisome. The endoplasmic reticulum (ER) signal sequence leads the ribosome to the ER, where proteins are destined to organelles of the secretory pathway: Golgi, plasma membrane, lysosome, or extracellular space.

Nascent secretory proteins are marked for cotranslational translocation into the ER by the presence of an amino-terminal ER signal sequence (see Table 4.2) that contains one or more positively charged amino acids followed by a continuous stretch of 6 to 12 hydrophobic residues. As the signal sequence emerges from the ribosome, it is recognized by the signal recognition particle (SRP), a ribonucleoprotein, that docks the ribosome to the ER membrane by interaction with the SRP receptor. Upon binding of GTP to the SRP and its receptor, the ribosome and the nascent chain are transferred in close proximity to the Sec61 translocon complex on the cytosolic face of the ER membrane. As the nascent polypeptide emerges from the luminal side of the translocon in an N-to-C direction, its signal sequence is cleaved by signal peptidase, translation is completed, and the protein assumes its folded configuration. Proteins without specific targeting sequences fully enter the ER lumen. For proteins destined to membranes, transmembrane domains consisting of approximately 20 largely apolar amino acids anchor the protein to the ER membrane lipid bilayer.

From the ER, proteins are transported to the plasma membrane and secreted or integrated into the membrane or targeted to endosomes; alternatively they are transported to the Golgi, lysosomes, and other organelles or retained in the ER as their final destination.[62] Transport through the secretory pathway is mediated by vesicles, and sorting motifs within proteins dictate the selective incorporation of cargo proteins into vesicles and their delivery to the intended destination.

On achieving transport competence, proteins are granted access to higher-ordered membrane domains termed ER exit sites. At ER exit sites, membrane-bound and soluble proteins are concentrated into transport vesicles for trafficking to a network of smooth membranes called the *ER-Golgi intermediate compartment* (ERGIC). COPII complex, composed of coat proteins, concentrates and packages the protein cargo into vesicles. COPII binds to cargo molecules either directly, if they span the membrane, or through intermediate cargo receptors and then provides some of the force that causes vesicle budding, thereby linking cargo acquisition to vesiculation.

ER-resident proteins are selectively sequestered in the ER, both for the absence of export signals and to the presence of ER retention signals. Soluble luminal ER resident proteins are retained through a C-terminal ER tetrapeptide retention motif KDEL. Frequently, transmembrane proteins have either a C-terminal dilysine motif KKXX or an Nt diarginine motif XXRR, or variants thereof for transmembrane proteins. However, it is more accurate to indicate ER localization signals as "retrieval motifs" because proteins bearing these signals can transiently escape from the ER into the ERGIC, from which they are returned to the ER through the retrograde vesicular transport.

For the KDEL motif of luminal ER proteins, a specific retrieval receptor has been identified, first in yeast and then in mammals. The KKXX motif has been shown to interact directly with the COPI coat protein complex that is involved in retrograde transport from the ER to the Golgi. Retrograde transport also serves to replenish the vesicle components lost as a result of anterograde (forward) transport. In conclusion, selective protein exit from the ER is achieved by monitoring/regulating (1) transport competence of nascent proteins, (2) capture of cargo in transport vesicles, and (3) protein retention/retrieval for ER-localized proteins.

Intra-Golgi Transport and Protein Processing

The Golgi complex comprises a stack of flattened, membrane-bound cisternae that is highly dependent on microtubules for structural integrity. The stack of cisternae can be subdivided into three parts referred to as *cis, medial*, and *trans*, with the *cis* and *trans* sides facing the ER and the plasma membrane, respectively. Both the *cis* and *trans* faces are associated with tubulovesicular bundles of membranes. The ERGIC comprises the bundle on the *cis* side of the Golgi stack and is the site where incoming proteins from the ER are sorted into those directed for anterograde or for retrograde transport. The tubulovesicular bundle at the *trans* side is the *trans*-Golgi network (TGN).

A major feature of the Golgi is polarity. The processing events are temporally and spatially ordered because the processing enzymes have a characteristic distribution across the Golgi stack. In the Golgi, different types of modifications take place (e.g., proteolytic processing, protein *O*-glycosylation and elaboration of N-linked chains, phosphorylation or sulfation of oligosaccharides, and sulfation of tyrosines as described later). The importance of protein glycosylation for human biology is underlined by the identification of many inherited human disorders that are caused by defects in these processes and cause clinical manifestations as described in Box 4.1.

Extensive analysis has failed to reveal a clear retention motif enabling subdomain-specific retention of resident Golgi proteins. Two possible models have been proposed. One model is *retention by preferential interaction with membranes of optimal thickness*. It is based on the finding that the transmembrane domains of Golgi proteins are shorter than transmembrane domains of plasma membrane proteins. These differences should allow a preferential interaction with the Golgi membrane lipid bilayer that is thinner than that of plasma membrane. The other model is *kin-recognition/oligomerization*. It postulates that proteins of a given subdomain of the Golgi membrane can aggregate into large detergent-insoluble oligomers as a way of minimizing lipid-protein contact. This would prevent the entry of proteins into the vesicles and thus their traffic to more distal cisternae. There is evidence in support of both models.

Cargo proteins exit the ER in COPII-coated vesicles that enter the ERGIC and are ultimately delivered to the *cis*-Golgi either in vesicles or along extended tubules. However, the mechanism whereby cargo proteins move across the Golgi complex from *cis* to *trans* remains controversial. Two models have been proposed. The vesicular transport model contends that anterograde transport occurs in vesicles or tubules that traffic cargo in an anterograde direction. The second suggests that there is a cisternal progression and maturation. This alternative model proposes that Golgi cisternae are not fixed structures but move forward from the *cis* side to the *trans* side generating an anterograde movement. As cisternae mature, resident Golgi proteins that belong to more *cis*-like cisternae must be selectively pinched off in vesicles and trafficked back to the *cis* side of the Golgi stack. This would occur by COPI-mediated retrograde vesicular transport. Although which of

BOX 4.1 Human Glycosylation Disorders

In humans, the three main glycosylation pathways are the *N*- and the *O*-glycosylation and the glycosylphosphatidylinositol (GPI) anchoring. Approximately 2% of the human genome encodes enzymes critical in glycosylation reaction, such as glycosyltransferases (GTs), glycoside hydrolases (GHs), or glycosidases, nucleotide sugar transporters.[63]

Glycosylation pathways intersect with glucose, lipid, and isoprenoid metabolism, expanding the number of players involved and the effects of these key protein modifications. Nearly 70 inherited glycosylation disorders have been identified so far, and this number is steadily increasing because of the progress in the technology of DNA sequencing and in mapping mutations. The characterized mutations combined with the biochemical lesion and with the clinical manifestations are classified in the congenital disorders of glycosylation (CDG) database (https://rarediseases.org/rare-diseases/congenital-disorders-of-glycosylation/). Abnormalities in *N*-glycosylation cause severe myasthenic syndromes caused by hypoglycosylation of the acetylcholine receptor that affects the signal transmission at the neuromuscular plaque. Others cause neurologic disorders. Hematologic disorders of glycosylation in particular are exemplified by hemolytic transfusion reactions due to differences in α-Gal(NAc) transferase alleles between individuals determining the ABO subtypes as well as differences in less prominent glycan antigens. In liver disorders, patients can manifest with bleeding due to aberrations in N-glycosylation of fibrinogen associated with a prolonged prothrombin time. Paroxysmal nocturnal hemoglobinuria (PNH) is a well-known, rare acquired hemolytic anemia arising from a somatic mutation in hematopoietic stem cells in the *PIGA* gene essential in the first step of biosynthesis of the GPI anchor for numerous cell surface proteins. The effects in red blood cells are the most prominent, resulting in hemolysis due to aberrant complement activation; patients are also at high risk for thrombosis due to loss of GPI-anchored proteins on monocytes and platelets (glycosylation disorders are reviewed in Freeze et al.[64]).

these models is correct is currently unclear, a majority of the experimental data support the cisternal maturation model. In particular, technical progress in live-cell imaging provided evidence supporting a very dynamic nature of this organelle as expected by the progression/maturation model.

The TGN is an important site of intracellular sorting, where proteins bound for lysosomes or regulated secretory vesicles are separated from those entering the constitutive pathway leading to the plasma membrane. The secretion process is called exocytosis. The molecular basis for diversion of proteins into lysosomes and regulated secretory granules are described later.

Sorting Into Lysosomes

Lysosomes are acidic (pH of approximately 5.0 to 5.5), membrane-bound organelles containing numerous hydrolytic enzymes designed to degrade proteins, carbohydrates, and lipids. Soluble hydrolases are selectively marked for sorting into lysosomes by phosphorylation of their *N*-linked oligosaccharides that creates the mannose-6-phosphate (M6P) sorting signal. On arrival at the TGN, the M6P-modified hydrolase is bound by a cargo receptor, the M6P-receptor (M6P-R), which delivers it first to a "late endosomal compartment," where the low pH releases the hydrolase from the M6P-R. Subsequently, the hydrolase is delivered to the lysosome, and the M6P-R is recycled from the endosomes through retromer-coated vesicles to the TGN to be reused.

The motif responsible for targeting M6P-R to lysosomes is YSKV and is recognized by all three distinct adaptor protein (AP) complexes (AP-l, -2, and -3) that contribute to delivery of cargo to lysosomes by linking cargo acquisition to vesiculation. Cargo recruitment occurs in a manner similar to that described for the COPI- and COPII-dependent vesicles, except that the cytosolic coat complex is clathrin. In addition to luminal hydrolases, lysosomes also contain a wide array of membrane proteins that are targeted to lysosomes via one of two consensus motifs: (1) YXXe, where X is any amino acid and e is any amino acid with a bulky hydrophobic side chain, and (2) a leucine-based motif (LL or LI). Trafficking of these membrane-bound proteins to lysosomes is indirect, proceeding first to late endosomes or the plasma membrane before their retrieval to lysosomes. Failure to accurately target lysosomal hydrolases underlies two well-known human diseases, Hurler syndrome, and I-cell disease. *Hurler syndrome* is caused by a mutation in a hydrolase responsible for breakdown of glycosaminoglycans that prevents the hydrolase from acquiring the M6P modification, consequently preventing targeting to lysosomes. Similarly, in *I-cell diseases*, undigested material accumulates in lysosomes because of a mutation in the enzymes that create the M6P modification, causing missorting of lysosomal hydrolases.

Targeting of Mitochondrial Proteins

The mitochondrion is an essential cellular compartment in eukaryotes. Although it contains its own genome organized in a circular DNA molecule and an independent transcriptional/translational machinery, 98% of the approximately 1500 proteins that constitute the mitochondrial proteome are encoded by nuclear DNA and are imported from the cytosol after their synthesis. A small number of highly hydrophobic proteins is encoded by mtDNA and transcribed and synthesized inside the organelle.

Like nuclei, mitochondria have two membranes: the outer membrane (MOM) contacts the cytosol, whereas the inner membrane (mitochondrial import machinery [MIM]) forms numerous invaginations named *cristae*, where the enzymes reside that synthesize ATP through reactions of the electron transport chain and oxidative phosphorylation. The MOM is permeable to small molecules (less than 5 kDa) and ions, whereas the inner membrane is highly impermeable, a property essential to create an electrochemical gradient necessary to drive the synthesis of ATP. Protein transport into mitochondria appears to be unidirectional because no proteins are known to be exported from mitochondria. Posttranslational translocation and sorting of proteins into the various mitochondrial subcompartments are achieved by the concerted action of translocases. Precursor proteins usually have one of two targeting signals: (1) an amino-terminal presequence that is generally between 10 and 80 amino acids long and forms an amphipathic α-helix, which is rich in positively charged, hydrophobic, and hydroxylated amino acids (see Table 4.2); or (2) a less well-defined, hydrophobic targeting sequence distributed throughout the protein. The translocase of the outer membrane (TOM) complex functions as a single entry point of incoming precursors into the mitochondria and is crucial for the biogenesis of the organelle and for the viability of eukaryotic cells. After crossing the outer membrane, proteins segregate according to their signals and recognize two distinct translocases of the inner membrane (TIM23 and TIM22). The intermembrane space import and assembly machinery (MIA) drives the import of proteins with cysteine-rich motifs, the sorting/assembly machinery (SAM) inserts precursors of proteins with a transmembrane β-barrel domains in the MOM, and the MIM imports outer membrane proteins with α-helical transmembrane segments after their recognition by the TOM complex.[65] Interestingly, cryoelectron microscopy images in cells show that translation-arrested cytosolic ribosomes are in close proximity of the surface of mitochondria. These ribosomes are organized in the clusters with the TOM complex, suggesting localized translation of mitochondrial proteins.[66]

In the context of cell biology, mitochondria play relevant roles in apoptosis, in the communication with the ER, and in oxidative stress. Among the proteins associated with the cytosolic side of MOM, those of the Bcl-2 family have both proapoptotic or antiapoptotic functions. BCL-2 family proteins function through direct protein-protein interactions. When BH3-only proteins are released by antiapoptotic BCL-2-like family members, they promote homo-oligomerization of the effector proteins BAX and BAK and induce mitochondrial outer membrane permeabilization, release of cytochrome c, and activation of the caspase cascade. BCL-2–mediated antiapoptotic effects are critical to the survival of CLL cells and inhibition of BCL-2 in CLL has led to complete responses even in relapsed, refractory CLL[67]; expansion of inhibition of BCL-2 and other antiapoptotic proteins in CLL and other hematologic malignancies is focus of intense studies.

Targeting of Peroxisomal Proteins

Peroxisomes are membrane-bound compartments that perform key roles in lipid metabolism and convert ROS. In this organelle, hydrogen peroxide is rapidly degraded by catalase to prevent oxidative reactions that have potential damaging effects on cellular structures. A single membrane surrounds the peroxisome that lacks a genetic system and transcriptional/translational machinery. All peroxisomal proteins are nuclear encoded. Their mRNAs are translated on cytosolic-free ribosomes, and proteins are imported posttranslationally by proteins called peroxins (Pex) that recognize peroxisomal targeting signals (PTSs) (see Table 4.2). Pexs function as cargo receptors; they bind cargo proteins in the cytosol, release them into the matrix, and cycle back to the cytosol. Experimental evidence suggests the existence of two routes by which peroxisomal matrix proteins can reach peroxisomes, one direct route and one via the ER.[68,69]

Sorting into Regulated Secretory Granules

In regulated secretion, proteins are condensed into stored secretory granules that require an appropriate stimulus for release from the cell. After budding from TGN, the granule proteins are concentrated (up to 200-fold in some cases) by selective removal of extraneous contents from clathrin-coated vesicles. Mature secretory granules are thought to be stored in association with microtubules until the stimulation of a surface receptor triggers their exocytosis. One example of stimulus-induced exocytosis is the binding of a ligand to the T-cell antigen receptor (TCR) complex on a cytotoxic T lymphocyte. Conjugation of a cytotoxic T cell with its target causes its microtubules and associated secretory granules to reorient toward the target cell. Subsequently, the granules are delivered along microtubules until they fuse with the plasma membrane, releasing their contents for lysis of the target cell. Following release of the granule contents, the granule membrane components are internalized and transported back to the TGN, where the granule can be refilled with cargo proteins.

PROTEIN FOLDING AND POSTTRANSLATIONAL MODIFICATIONS

Protein Folding

As the polypeptide emerges from the ribosome, it must fold to become a mature functional protein. The conformation of a protein is dictated primarily by the primary structure. Some proteins can spontaneously acquire their mature three-dimensional conformation as they are synthesized in the cell. However, most polypeptides require assistance from other proteins for proper folding, so-called molecular chaperones that either directly assist folding reactions and/or prevent aberrant interactions, such as aggregation that can occur in a densely packed environment such as the cytosol of eukaryotic cells (protein concentration of 200 to 300 mg/mL). Most molecular chaperones are heat-shock proteins (Hsps) and in particular members of the Hsp70 family. Chaperones bind to short sequence protein motifs, in many cases containing hydrophobic amino acids. By undergoing cycles of binding and release (linked to ATP hydrolysis), chaperones help the nascent polypeptide to find its native conformation. Examples are hiding of hydrophobic sequence motifs in the protein interior so that they no longer contact the hydrophilic environment of the cytosol or assembly into multisubunit complexes with other proteins. The population of chaperones that assist folding and assembly in the cytosol is distinct from those that operate within the ER or mitochondria.

Protein Modifications

Modifications of the polypeptide chains introduce new functional groups to proteins and extend the repertoire of the standard amino acid residues. More than a hundred modifications have been identified, and modifications occur during (cotranslationally) or after synthesis of the polypeptide (posttranslationally). Most of the reversible modifications are carried out by enzymes that catalyze the transfer of a chemical group from a donor molecule to the target amino acid. In contrast, proteolytic cleavage of precursor proteins to generate mature products is generally irreversible. The most common protein modifications include acetylation, methylation, myristoylation, prenylation, phosphorylation, sulfation, γ-carboxylation, ubiquitination, sumoylation, and proteolysis. Protein modifications are critical in numerous physiologic processes and central to inherited and acquired diseases. Histone proteins undergo posttranslational modifications (PTMs), such as methylation, acetylation, and others, that modulate the epigenetic code; their specific function is reviewed in Chapter 2. Here are some features of the most common protein modifications:

- *Acetylation*: approximately 80% to 90% of human proteins are cotranslationally, irreversibly N-acetylated (acetyl group: $COCH_3$). Ribosome-associated Met-aminopeptidases and acetylases cotranslationally cleave off the Nt methionine and acetylate the second residue, respectively. Consequences of Nt-acetylation are manifold, ranging from determining subcellular localization, to regulating protein-protein interactions, to protein folding and other functions. Reversible acetylation can occur posttranslationally on the ε-amino group of lysines, abolishing its positive charge. Besides phosphorylation, lysine acetylation is perhaps the most abundant and important PTM in cell signaling and metabolism.[70]
- *Methylation*: is the reversible addition of a methyl group (CH_3) to lysine or arginine residues. This modification increases the hydrophobicity of the protein-altering protein-protein interactions. Protein arginine methylases are explored as therapeutic targets in leukemia and other hematologic malignancies.[71,72]
- *Phosphorylation*: introduces a charged and hydrophilic phosphate group in the side chains of serine, threonine, or tyrosine with a ratio of occurrence of 1000:100:1 and represents a flexible mechanism for cells to respond to external signals and environmental conditions. Phosphorylation is reversed by the action of protein phosphatases that remove the phosphate group. It has been estimated that the human genome encodes approximately 500 protein kinases and 100 protein phosphatases. The catalytic or biologic activity of many enzymes is transiently regulated by reversible phosphorylation (e.g., switched "on" or "off" by phosphorylation or dephosphorylation, respectively). There are several prominent examples of mutations in tyrosine kinases or their involvement in translocations that result in loss of response and regulation in hematologic diseases, such as mutations in FLT3 in myeloid leukemia, in JAK2 in polycythemia vera, and translocations involving the ABL tyrosine kinase in t(9;22) in chronic myeloid leukemia. All result in constitutive activation providing proliferative and survival advantage to malignant clones.
- *Sulfation:* this modification occurs at tyrosine residues and is catalyzed by tyrosyl-protein sulfotransferases (TPSTs), which are membrane-associated enzymes of the *trans*-Golgi network. An unusual nucleotide, a 3′-phosphoadenosine 5′-phosphosulfate (PAPS), is the universal sulfate donor for TPST-catalyzed reactions. Addition of sulfate occurs almost exclusively on secreted or membrane proteins and is believed to play a role in the modulation of protein-protein interactions. Sulfation is critical in blood coagulation (coagulation factors V and VIII), various immune functions, intracellular trafficking, and ligand recognition by several G protein–coupled receptors.
- *γ-Carboxylation:* vitamin K is an essential cofactor for the enzyme γ-glutamyl carboxylase (GGCX) that converts glutamate into γ-carboxyglutamate in numerous factors of the clotting cascade, specifically factors II, VII, IX, and X. γ-Glutamyl carboxylation introduces affinity for calcium ions, and its role in coagulation is described in more detail in Box 4.2.

BOX 4.2 Protein γ-Carboxylation: A Rare Posttranslational Modification Crucial for Life

γ-Carboxylation of a cluster of glutamic acid residues near the amino termini of factors involved in blood coagulation are essential for these proteins to bind calcium ions and for their proper biologic activity. These factors are prothrombin (factor II) and factors VII, IX, and X, which are involved in the coagulant response, and protein C and S with critical roles in the antithrombotic pathway that limits coagulation. In addition, protein Z and GAS6 are also γ-carboxylated. Protein Z functions as cofactor in inhibition of factor Xa and GAS6 contributes to αIIbβ3 integrin activation on platelets and release of tissue factor by endothelial cells.[73]

This PTM is catalyzed by γ-glutamyl carboxylase, an endoplasmic reticulum (ER) membrane protein, that binds the substrate protein via a sequence motif on the amino terminal side of the glutamate residues to be carboxylated and releases the protein after all glutamates in the cluster have been carboxylated. Its obligate cofactor, reduced vitamin K, is produced by the action of vitamin K-epoxide reductase (VKOR), which converts oxidized vitamin K to the reduced form. The activity of VKOR is inhibited by warfarin, a potent anticoagulant compound. γ-Carboxylase homozygous null mutants manifested dramatic effects on development with partial midembryonic loss and postnatal hemorrhage. Similar effects were observed in prothrombin or factor V–deficient mice. Thus the results of these studies have suggested that the functionally critical substrates for γ-carboxylation are primarily restricted to components of the blood coagulation cascade, although bone proteins osteocalcin and matrix Gla- (γ-carboxyglutamate) protein also require processing by γ-carboxylation for full activity. These results highlight the importance of this rare protein modification for blood coagulation.

- *Ubiquitination:* the role of ubiquitination is manifold. It marks proteins for degradation (explained in detail later) and alters their function, their location, and protein-protein interaction. Ubiquitination is achieved by three main steps involving ubiquitin activating and conjugating enzymes, and ubiquitin ligases. Single (monoubiquitination) or multiple (polyubiquitination) ubiquitins can be attached to lysines in target proteins with differing consequences.
- *Sumoylation:* **s**mall **u**biquitin-related **mo**difier (SUMO) proteins are similar to ubiquitin and hence called ubiquitin-like (Ubl). The small peptide SUMO is among the best characterized Ubl, and more than 50 proteins are modified by SUMO addition.

Additional modifications form anchors for membrane association. Among the most important of these modifications are:

- *Myristoylation:* irreversible attachment of a 14-carbon myristoyl group to the Nt glycine residue of a protein allows association of the target protein with membranes, other proteins, or lipids.
- *Prenylation:* involves attachment of the 15-carbon farnesyl group or 20-carbon geranyl group to acceptor proteins that harbor a CAAX consensus sequence (C = cysteine, AA = any aliphatic amino acid except alanine, X = any amino acid) at the C-terminus. Examples of prenylation occur on RAS and RAB protein family members and control their intracellular membrane traffic (see later). Lack of prenylation generates severe phenotypes.

The aforementioned modifications are in general reversible, whereas proteolysis is generally considered an irreversible PTM:

- *Proteolysis:* results in cleavage of the polypeptide chain at a specific site during its maturation (proinsulin to insulin) or occurs upon secretion of the polypeptide's inactive form (zymogen). The need for and specific timing of proteolysis prevent unwanted toxic effects of the processed protein in the cell, as is the case for digestive proteases, or direct activation of proteins to specific sites and contexts, as is the case for activation of coagulation factors at sites of damaged blood vessels. Proteolytic processing of propolypeptides into their mature forms occurs after the Arg-Xxx-Lys-Arg motif and is mediated by the protease FURIN. FURIN is ubiquitous and activates clotting factors, growth factors, and other proteases. Other members of the proprotein convertase (PC) family cleave after pairs of dibasic amino acids (e.g., Lys-Arg) and are expressed in specific cell types, such as neuroendocrine cells.

Additional enzymatic modifications (*N*-glycosylation, *O*-glycosylation, and attachment of a glycosylphosphatidylinositol [GPI] anchor) are discussed later and in Box 4.2.

In addition to enzymatic reactions, proteins can also undergo nonenzymatic modifications, such as during oxidative stress or in the presence of excess glucose in the blood, as in the case of hemoglobin glycation.

Protein Folding and Modifications in the Endoplasmic Reticulum

Protein folding in the ER is facilitated by protein chaperones, such as the Hsp70 family member BiP, and PTMs, such as asparagine(*N*)-linked-glycosylation and disulfide bond formation.[74] Folding begins cotranslationally and is enhanced by folding catalysts. For example, the proper pairing and formation of disulfide bonds is catalyzed by oxidoreductases, such as protein disulfide isomerase (PDI), that also shuffle nonnative disulfide bonds. In contrast to the highly reducing environment of the cytosol where disulfide bonds do not typically form, the lumen of the ER is highly oxidizing so that disulfide bond formation is favored.

Most proteins that enter the secretory pathway are modified by *N-glycosylation* which starts with the transfer of a core oligosaccharide from a lipid-linked dolichol donor to an asparagine residue within the consensus sequence N-X-S/T of a nascent polypeptide (X can be any amino acid except for proline). The N-linked oligosaccharide is composed of a glucose$_3$-mannose$_9$-*N*-acetylglucosamine$_2$ unit (Glc$_3$Man$_9$GlcNac$_2$) and is transferred to the asparagine residue by an ER oligosaccharyltransferase (OST). Further processing of the terminal sugars occurs in the ER and after the polypeptide transits the Golgi compartment. Many blood proteins (e.g., immunoglobulins, antiproteases, and coagulation factors) and many membrane proteins are glycosylated. The human A, B, and O blood-group system is defined by distinct glycosyltransferases. Both the A and B antigens are similar to the O antigen but contain additional residues: the A antigen contains an additional *N*-acetylgalactosamine, and the B antigen an extra galactose residue attached to the outer galactose. People with the O antigen carry antibodies against A and B, whereas people with the A or B antigen carry anti-B or anti-A antibodies, respectively, determining blood transfusion compatibility. The hormone erythropoietin requires a particular, complex type of *N*-glycan chains for its biologic function to stimulate erythropoiesis in vivo: recombinant erythropoietin that lacks its normal *N*-linked oligosaccharides when injected into humans is much less potent than the normal protein because it is degraded much faster than the endogenous, glycosylated protein. Thus glycans protect proteins from protease digestion and heat denaturation, confer hydrophilicity and adhesive properties, mediate protein-protein interactions, and promote protein folding and trafficking.

The ER is also the site of γ-carboxylation of glutamic acid residues (e.g., in the coagulation factors II, VII, IX, and X as described earlier and as detailed in Box 4.1). Another modification is the attachment of a GPI anchor to the C-terminal end of proteins with concomitant release of the GPI signal peptide. The GPI attachment promotes membrane association.

PROTEIN DEGRADATION

Endoplasmic Reticulum-Associated Degradation and the Unfolded Protein Response

In the ER, proteins undergo quality control, which ensures that only correctly folded proteins exit the ER. Misfolded proteins are extracted from the ER for *endoplasmic reticulum-associated degradation* (ERAD) (Fig. 4.9). ERAD occurs in three major steps: (1) detection by the ER quality control machinery and targeting for ERAD, (2) transport

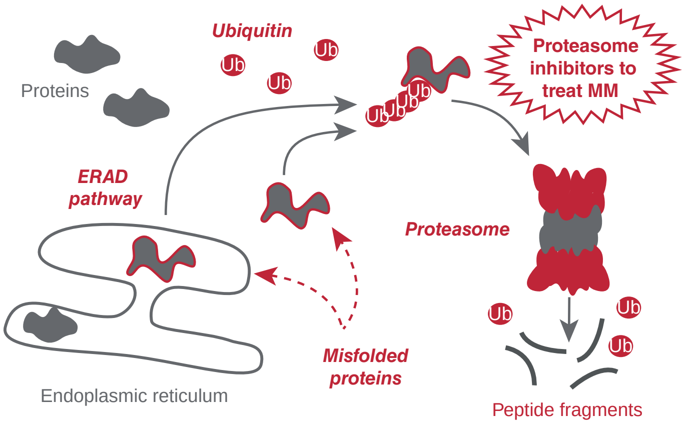

Figure 4.9 PROTEIN DEGRADATION PATHWAYS AND UNFOLDED PROTEIN RESPONSE. The major pathway of selective protein degradation in eukaryotic cells uses ubiquitin as a marker that targets proteins for rapid proteolysis thanks to the proteasome complex. This pathway deals also with misfolded proteins that could accumulate in the endoplasmic reticulum (ER) during stress or disease. Misfolded proteins are extracted from the ER for *endoplasmic reticulum-associated degradation (ERAD)*. Proteasome inhibitors are the therapeutic backbone for the treatment of several hematologic diseases, such as multiple myeloma *(MM)*.

across the ER membrane into the cytosol, and (3) ubiquitylation and degradation by the proteasome.

The ER monitors the amount of unfolded protein in its lumen. When that number exceeds a certain threshold, ER sensors activate the so-called unfolded protein response (UPR). A number of cellular insults can disrupt protein folding and cause accumulation of unfolded proteins in the ER lumen. The UPR is an adaptive response signaled through three ER-localized transmembrane proteins PERK, IRE1, and ATF6. These proteins function as sensors through the properties of their ER-luminal domains and trigger a concerted response through the function of their cytosolic domains aimed to (i) limit accumulation of unfolded protein through reduction of protein synthesis, to (ii) increase the degradation of unfolded protein, and to (iii) increase the ER protein-folding capacity. PERK-mediated phosphorylation of eIF2α attenuates general mRNA translation while increasing translation of the transcription factor ATF4 that induces transcription of UPR genes. IRE1 carries protein kinase and endoribonuclease activities that, upon activation, mediate unconventional splicing of a 26-base intron from the basic leucine zipper (bZip) transcription factor XBP1 mRNA. ATF6 is transported to the Golgi compartment upon accumulation of unfolded protein in the ER lumen, where it is cleaved by two proteases to release its cytosolic fragment also containing a bZip-transcription factor. Both XBP1 and ATF6 upregulate transcription of ER "stress elements" to correct protein folding. If the UPR adaptive response is not sufficient to correct the protein folding defect, the cells enter apoptotic death. The ER in this role is regarded as a sensor of perturbations of cell homeostasis and both activation and defects of the UPR are central to many disease processes, ranging from metabolic, neurologic, and infectious diseases to cancer.[75] In hematologic malignancies, such as multiple myeloma, the UPR response mediated by the IRE1 axis is highly activated and essential for cell survival. The role of the UPR in cancer survival and cancer immunogenicity is reviewed in Vanacker et al.[76]

Protein Degradation by the Proteasome

Protein degradation serves to regulate protein levels and to eliminate mutated proteins that would otherwise result in accumulation of misfolded proteins. As described earlier, proteins targeted for degradation are tagged via polyubiquitination and ferried to the 26 S *proteasome*, an ATP-dependent protease complex and multisubunit molecular machinery specialized in protein destruction (see Fig. 4.9). Proteasomes are located both in the nucleus and in the cytoplasm, and peptides and amino acids derived from protein disposal are recycled. The ubiquitin-proteasome system regulates a wide array of cellular processes, including differentiation, tissue development, induction of inflammatory responses, antigen presentation, cell cycle progression, and programmed cell death.[77] In addition, according to the pattern of modification of the target proteins (monoubiquitination, polyubiquitination) different proteins can trigger DNA repair (monoubiquitination of Nt tails in histones) or be subjected to endocytosis (monoubiquitination of surface receptors). Discoveries over the past several years have highlighted the central role of the ubiquitin-proteasome system in the treatment of hematologic malignancies. Targeting of the transcription factors IKZF1 and IKZF3 in multiple myeloma to the proteasome via enhanced docking to the cereblon E3 ubiquitin ligase complex by the small molecule thalidomide,[78,79] inhibition of the proteasome in multiple myeloma,[80] and most recently the development of proteolysis-targeting chimeras (PROTACs) and other technologies to therapeutically degrade proteins[81] and take advantage of the proteasome's role in cellular function.

Several pathways as described earlier serve to degrade RNA, and the proteasome serves to degrade proteins.

Autophagy

In a process called *autophagy*, cellular components and organelles are captured and degraded. Cellular material is sequestered inside double-membrane vesicles, called autophagosomes, and degraded upon fusion with lysosomal compartments. Raw precursors are subsequently recycled for new biosynthesis. Autophagy at baseline serves to demolish damaged organelles or cytosolic components; autophagy is also stress responsive to catabolize cellular components to maintain adequate energy supply and cell homeostasis. An increasing body of evidence suggests that autophagy plays an important role in development and cell differentiation by facilitating cell and tissue remodeling. Remarkably, the basis for terminal erythrocyte maturation, which involves elimination of mitochondria, ribosomes, and other organelles, is now known to be partly dependent on autophagy and in particular mitophagy, the elimination of mitochondria. Defective autophagy compromises fitness of an organism. Defective autophagy increases susceptibility to tumorigenesis, neurodegenerative disorders, liver disease, aging, inflammatory diseases, and defective host defense against pathogens.

CONCLUSIONS

Control of gene expression is a highly regulated process with several steps, including: (1) DNA transcription into RNA, (2) splicing and maturation of RNA, (3) modification of RNAs affecting their stability and localization, (4) export of RNAs from the nucleus to the cytoplasm, (5) regulation or RNA degradation and storage in RNA granules and membraneless organelles, (6) translation of mRNAs into proteins by polyribosomes, and (7) protein folding, sorting, modification, and degradation. Perturbations in any of these steps, or in their combinations, can result in hematologic disease but also possess the potential of therapeutic intervention. RNA metabolism and RNA biologics have entered drug development as targets or as actual therapeutics with great promise, respectively. The deciphering of RNA modifications and the ability to perturb the RNA methylase, eraser, and reader proteins represent novel therapeutic opportunities in MDSs and leukemia.

The mechanisms regulating protein synthesis, processing, degradation, and transport have undergone intensive investigation. Protein motifs and their cognate receptors have been identified for many intracellular sorting and processing reactions. Advanced technologies have identified numerous players of the proteasome and the mechanistic basis of protein degradation, resulting in numerous therapeutics exploiting this pathway in hematologic malignancies.

CHAPTER 5

GENOME EDITING

Matthew Porteus

Genome editing is a rapidly developing field in which the genome of cells is modified with single nucleotide precision.[1,2] This degree of precision is not achievable by other forms of genetic engineering, including contemporary lentiviral vectors, recombinases, or transposases. Not only is genome editing precise in the location of the changes made, but it is highly flexible and robust in the types of changes that can be made, including creating new mutations at specific genomic sites, the conversion of a single nucleotide to another nucleotide, and the insertion of cassettes of genes at specific genomic sites. Genome editing is also known as "gene editing," but because the entire genome can be modified, not just genes, a more precise and comprehensive term is genome editing. Genome editing has become a powerful research tool and has generated tremendous excitement as a therapeutic approach to treat or cure disease. When genome editing is used therapeutically, it is a specific and precise approach that falls under the broader gene therapy umbrella.[3] This chapter will describe the process of genome editing, explain different types of edits that can be made to the genome, use specific hematologic diseases as examples of how genome editing is being developed therapeutically, and ends with a brief discussion of technical and ethical issues of applying genome editing outside of the ex vivo manipulation of somatic cells.

DOUBLE-STRANDED DNA BREAKS: THE BASIS OF NUCLEASE-BASED GENOME EDITING

The spontaneous frequency of a mutation occurring at a specific site in a nontransformed human somatic cell is on the order of 10^{-8} to 10^{-9}. Thus the ability to create specific mutations at a specific site in a reproducible fashion at high frequency is not generally possible. Moreover, the frequency of spontaneous targeted integration (the insertion of a DNA fragment at a specific location in the genome [also called gene targeting]) is on the order of 10^{-6} (only one in a million cells will undergo this process).[4] The identification of cells having undergone gene targeting can be increased by several orders of magnitude by using positive and negative selection strategies.[5–7]

The frequencies of targeted mutation and targeted integration change dramatically if a DNA double-strand break (DSB) is created at the target site.[8–10] Using contemporary methods to create DSBs, the frequency of targeted mutations, even in primary human cells, can now exceed greater than 90% of alleles and the frequency of targeted integration can routinely exceed greater than 50% of alleles. Therefore a site-specific DSB increases the frequency of targeted genome sequence changes (genome editing) by 6 to 9 orders of magnitude and is a key foundational principle of genome editing. This natural process can be manipulated experimentally or therapeutically to modify the cell's endogenous genome, making genome editing both a powerful research tool and potential therapeutic modality.

The basis on which a DSB increases genome editing by this enormous magnitude is that a genomic DNA DSB is a dangerous event to the cell. It causes the loss of chromosomal integrity (it separates the telomere from the centromere). Dozens of DSBs occur spontaneously in all living cells per day, caused by variety of different genomic insults. Cells have developed redundant mechanisms to respond to and repair DSBs. The two most prominent are nonhomologous end-joining (NHEJ) and homologous recombination (HR).[11,12]

In NHEJ, a complex of proteins holds the broken ends together while the ends are processed to allow ligases to seal the two ends back together. Conceptually, the ends are stitched back together. In general, the NHEJ process is quite accurate, with the two ends being joined precisely 70% of the time, but in the remaining instances the ends are joined after the loss or gain of nucleotides at the site of the break (insertions and deletions [indels]). The NHEJ repair pathway is active throughout the cell cycle.[13] Inactivation of genes needed for NHEJ leads to genomic instability but not to immediate cell death.[14,15]

HR is a biochemically more complex process in which a much larger number of proteins are involved. In mitotic mammalian cells, the mechanism by which cells repair DSBs by HR is through the "synthesis-dependent strand annealing" (SDSA) mechanism (Fig. 5.1).[16,17] Conceptually, the cell uses an undamaged homologous piece of DNA as a template to synthesize new DNA and then uses the newly synthesized DNA to paste into the damaged DNA to fix the DSB. It can be thought of as a "copy and paste" mechanism. An important feature of the SDSA mechanism of repair is that the template DNA is not physically transferred into the break. Instead, it is the information in the template DNA that the recombination machinery copies and transfers into the site of the break. The normal and natural template DNA is the sister chromatid. The HR repair pathway is thought to be active only in S/G_2 of the cell cycle (when a sister chromatid is present). Mutations in important HR genes can cause cell lethality within a single round of replication.[18]

BASE EDITING

The most well-developed genome editing system that does not require the creation of a DSB in the genome is base editing.[19–23] In base editing, single nucleotide changes are made by deamination of either adenine (adenine base editors [ABEs]) and cytosine (cytosine base editors [CBEs]). The natural repair mechanisms that exist to convert deaminated adenine and cytosine back to adenine and cytosine are inhibited as part of the base editing system. In ABEs the adenine is thus converted to a guanine, whereas with CBEs the cytosine is converted to a thymidine.

The base editing systems consist of a Cas9 (Cas9 is an enzyme that cuts DNA at specific sites to which it is guided by an attached "guide RNA" [gRNA] sequence—discussed in more detail later), which has been engineered such that it makes a break (nick) in only one strand of the DNA and is fused to a deamination enzyme and an inhibitor of a deglycosylase. The inhibitor of the deglycosylase blocks the natural repair of deaminated bases. The large Cas9-deaminase-inhibitor complex is directed to the site of base editing by complexing with its gRNA. It is the engineered sequence of the gRNA that targets the complex to the correct site in the genome.

Since the first reports of the development of the CBE and ABE systems in cancer cell lines, both have been applied therapeutically as well. These applications include making new stop codons in genes to create null versions of the gene. Because base editors do not generate a DSB, they can be applied to make multiplex edits

Figure 5.1 OVERVIEW OF NUCLEASE-BASED GENOME EDITING

without a high risk of causing translocations such as can occur when using multiplexing nuclease-based editing.[21] In addition to making new stop codons, base editors have also now been applied ex vivo to genetically convert the mutation that causes sickle cell disease to a hemoglobin (Hb) variant called Hb Makaser (HbM). In contrast to HbS in which a valine is at position 6 of the HBB protein, in HbM an alanine is at position 6, a harmless change.[22,23] Finally, base editing has been applied in vivo in a mouse model of a Hutchinson-Gilford progeria (a genetic premature aging disease in humans) and been demonstrated to increase the longevity and improve the symptoms.[24]

The limit of base editing is that only single nucleotide changes can be made, although simultaneous single nucleotide changes can be made at multiple sites, and that the ABE and CBEs still do not allow every possible single nucleotide substitution to be made. Although the avoidance of a DSB has been described as a possible way to reduce genotoxicity compared with nuclease-based genome editing, the full scope of off-target effects of base editors on both genomic DNA and RNA are still being investigated.

OTHER GENOME EDITING SYSTEMS

In addition to nuclease-based genome editing and base editing systems, there are multiple other genome editing systems being developed, but they have not reached the same broad utility. These include non–nuclease-based adeno-associated virus (AAV) targeted integration systems,[25,26] peptide nucleic acid–based systems,[27] PRIME-editing systems,[28] targeted transposase systems,[29] and targeted recombinase systems.[30] It is likely that other systems will continue to be discovered. The range of genomic changes that can be made using these other systems can all be made at least as efficiently nuclease-based systems, but there are several types of genomic changes that can only be made using nuclease-based genome editing. The targeted insertion of large genes in primary cells, such as hematopoietic stem cells or T cells, can only be efficiently done using engineered nucleases, for example.

USING ENGINEERED NUCLEASES TO INITIATE THE GENOME EDITING PROCESS

For genome editing to become a practical methodology, one needed to develop nucleases that could be engineered to specifically recognize any site in the genome needed to be discovered.[31–33] There are now multiple engineered nuclease platforms. Each fundamentally achieves the same effect by creating a site-specific DSB. There are three major nuclease platforms that achieve specificity by protein-DNA recognition. These platforms include engineered meganucleases, zinc finger nucleases (ZFNs), and TAL effector nucleases (TALENs).[2,34] Although there is a relatively well-defined protein-DNA recognition code for TALENs, the recognition code for meganucleases and ZFNs is more obscure. These systems are workable but complex and less readily adapted to widespread use.

Fortunately, the field of genome editing was revolutionized by the discovery of a nuclease platform that achieved specificity through Watson-Crick base pairing rather than protein-DNA recognition—the CRISPR/Cas9 nuclease system.[35,36] In the CRISPR/Cas9 system, the multifunctional Cas9 protein is complexed to a 99-nucleotide gRNA. The gRNA has two parts—a 3′ scaffold that allows it to complex with Cas9 and a 5′ recognition sequence that determines the target site that Cas9 will cut. By designing the 5′ recognition sequence to bind to the desired genomic target (by Watson-Crick base pairing), the gRNA can be used to bring the Cas9 nuclease to the correct location. This activates its nuclease activity and cuts the DNA. The CRISPR/Cas9 nuclease system has transformed the field of genome editing not just because of the ease of designing gRNAs to desired genomic targets but also, for remarkable reasons still not completely understood, because CRISPR/Cas9 has exhibited high on-target activity with low off-target activity in essentially every cellular/animal system it has been tested in. Refinements have been made to increase activity and specificity, but the CRISPR/Cas9 nuclease worked extremely well "right out of the box."

The transformational importance of the CRISPR/Cas9 system was codified by the awarding of the Nobel Prize in Chemistry in 2020 to Emmanuelle Charpentier and Jennifer Doudna for their discovery that the nuclease could be reduced to the two-component single-gRNA/

Cas9 protein complex.[36] That achievement depended on vast amounts of earlier work that went into the discovery and understanding of the CRISPR system by many others who should also be recognized.[37,38]

GENOME EDITING USING ONLY A NUCLEASE AND NONHOMOLOGOUS END-JOINING REPAIR

There are a wide variety of changes to the genome that can be made by simply delivering the nuclease like CRISPR/Cas9 into a cell and creating a break. When a single nuclease is delivered, high frequencies of indels can be created at a specific site. These mutations can be used to: (1) inactivate the coding region of a gene; (2) inactivate a promoter region of a gene; and (3) inactivate an enhancer or silencer element modulating a gene, among many other things (Fig. 5.2).

While high frequencies of indels (>90%) can be generated using a nuclease targeting a single site, some of those indels may not result in complete inactivation of the target. The repaired gene remnant may exhibit some residual activity. By delivering nucleases targeting two sites in the same genomic region, very high frequencies of defined deletions can be created (>95% when optimized).[39,40] Using a two-nuclease system, defined segments of the genome can be removed, thus creating more definitive inactivation of a gene or genetic element (e.g., an enhancer or aberrant splice site). The frequency of deletions is highest when the region of the deletion is relatively short but can still be high for deletions of several thousand base pairs in some cases and can even create megabase deletions at reasonable frequency as well.

The two-nuclease approach for targeting sites on different chromosomes can generate high frequencies of translocations. For research this can be a useful method to interrogate the role of specific translocations in development and oncogenesis.[41,42] For therapeutic purposes, such translocations need to be evaluated as a potential safety issue.[43]

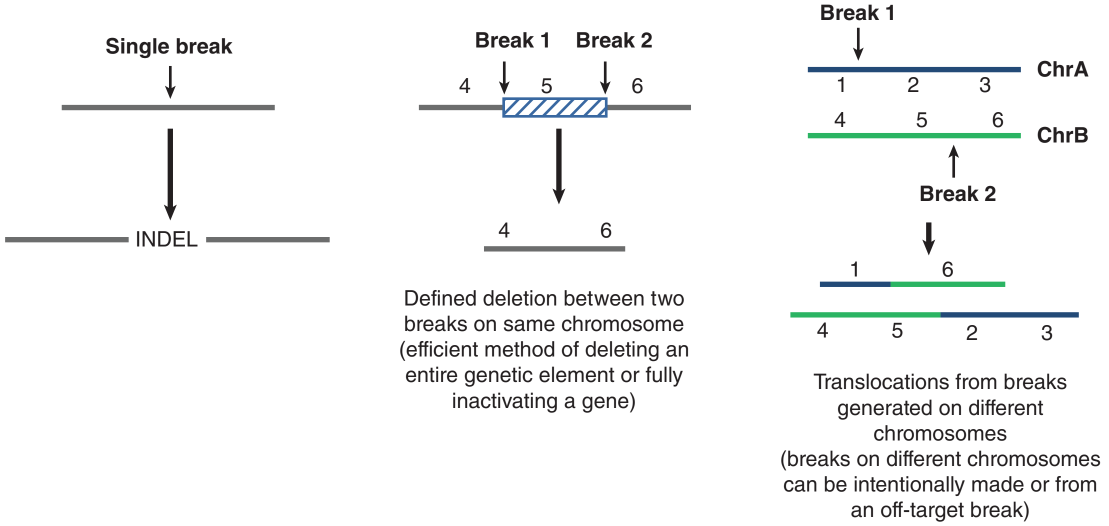
A BROAD RANGE OF GENOMIC CHANGES BY HOMOLOGOUS RECOMBINATION–MEDIATED GENOME EDITING

HR-based genome editing requires that both a nuclease and a donor DNA molecule be provided to the cell. In HR-based editing, the cell's natural HR machinery uses the engineered undamaged donor as the template for the repair of the nuclease-induced break. To differentiate HR that repairs a DSB using the sister chromatid as a natural form of repair from genome editing HR, the term "homology-directed repair" (HDR) has been coined to describe the application for genome editing (Fig. 5.3). In nuclease-based gene targeting, the donor vector needs to have flanking homology arms of greater than 400 bp (although shorter can work).[44] These relatively short homology arms are in contrast to the several thousand base pair homology arms needed for mouse ES cell gene targeting.

There are a wide variety of changes that can be made using HDR-based genome editing that can be used for both research and therapeutic purposes. These include:

1. Making single nucleotide changes to the genome, such as to revert a disease-causing genetic single-nucleotide variant;
2. Inserting a short stretch of nucleotides at specific location, such as to add an epitope tag to a protein;
3. Inserting a full complementary DNA (cDNA) or partial super-exon cDNA back into a gene to functionally correct downstream mutations;
4. Inserting one gene into another gene or replacing one gene with another gene. In this form of synthetic biology, the genome is being reprogramed to express the inserted gene under the control of the target gene's regulatory apparatus.
5. Inserting one gene into another gene without disrupting the target gene. Thus the knockin gene is now expressed along with the target gene in the cell.
6. Inserting promoter-gene cassette(s) into a safe harbor locus. A safe harbor is defined as a genomic location that if DNA is inserted into it, there would be no deleterious consequence. A safe harbor can be universal, in which it would safe to insert in all cell types or can be cell type specific, where insertion is safe in that cell type but not in another. There are many possible safe harbor options, but each needs to be carefully evaluated.

A version of HDR is to use a single-stranded oligonucleotide (ssODN) as a template rather than a gene targeting donor vector. The mechanism by which ssODNs are used by the cell to repair a DSB is not through the standard recombination pathway but instead through a pathway called "single-stranded template repair" (SSTR). SSTR does not require canonical HR genes such as Rad51 but instead requires genes in the Fanconi anemia family.[45,46] The nonnuclease targeted integration of single-stranded AAV vectors also requires genes from the Fanconi anemia family.[47] Presumably SSTR-based editing, like HR based editing, is harnessing a natural pathway that cells use to repair DSBs, but the natural function of SSTR, unlike HR, has not been well established.



Defined deletion between two breaks on same chromosome (efficient method of deleting an entire genetic element or fully inactivating a gene)

Translocations from breaks generated on different chromosomes (breaks on different chromosomes can be intentionally made or from an off-target break)

GENOTOXICITY THROUGH POTENTIAL OFF-TARGET NUCLEASE-INDUCED DOUBLE-STRAND BREAKS

Although all engineered nucleases are designed to have single site specificity, as proteins with biochemical properties, there is the possibility that because off-target binding (determined by standard on- and off-rates), they might create DSBs at unintended genomic sites. Because DSBs have the potential to create genotoxicity, the measurement and minimization of potential off-target breaks have been an important part of the genome editing field.[48]

There are multiple different methods to identify potential off-target sites, including bioinformatic methods, in vitro biochemical methods, and cellular-based methods. Each of these methods has its own strengths and weaknesses, and currently the approach to evaluating the specificity of nucleases used for translational purposes is to use a combination of approaches. In contrast to knockdown approaches using short-hairpin RNAs (shRNAs), it is remarkable that there have been no reports of off-target effects confounding an experimental result, and thus, for research purposes, using bioinformatics to identify guides with low probability of off-target cutting based on sequence homology has been adequate. The gold standard for measuring potential off-target effects is to quantify the frequency of indels using amplicon deep sequencing from the cell population of interest. Currently the sensitivity of this approach is reliable only down to the 0.1% level.

Because of the importance of specificity, there have been several engineered variants of the Cas9 derived from *Streptococcus pyogenes* (the most used source for Cas9 for ex vivo editing) with increased specificity.[49–53] The increased specificity has been obtained by targeting different biochemical properties of the Cas9 protein. However, some of these variants may have been overengineered and have lost on-target activity in the process of creating increased specificity. Care must then be used to identify which Cas9 is best designed for the specific project. Using these engineered specificity variants, there are now multiple examples of no measurable off-target indels being created using a given gRNA.

The potential for off-target breaks induced by a nuclease should also be put into context of the cell's robust ability to repair the wide variety and large number of DNA insults it is challenged with each day. These include tens of DSBs at random sites and thousands if not tens of thousands of other lesions, most of which occur randomly in the genome, including in tumor suppressors and oncogenes. In contrast to lentiviral vectors, there has been no description of a well-designed engineered nuclease causing lesions in a tumor suppressor or oncogene as an off-target event.

GENOME EDITING AS A RESEARCH TOOL

Genome editing, especially with the discovery and development of the CRISPR/Cas9 system, has become a powerful research tool in hematology. It is a genetic tool that now gives researchers the opportunity to genetically modify blood cells, both by NHEJ and HR, at frequencies that were once only available to yeast researchers. It has become the new standard to create genetically engineered models of human disease because zygote editing in animals has become so efficient. Animal models of human disease can now be more rapidly made in mice (including in different genetic backgrounds) and, even more importantly, beyond mice to other species. These nonmice animal models are likely to be more informative to the human condition than what was possible using in-bred laboratory mouse models.

The CRISPR/Cas9 system has also given researchers a tool to do whole genome genetic screens using libraries of gRNAs that target different parts of the genome. These screens were first focused on the coding regions of protein-coding genes but are now being applied to other parts of the genome as well. These screens allow mutations to be created simultaneously in a wide variety of genes and then the population of cells to be screened for changes in phenotype. The specific genes identified by CRISPR/Cas9 knockout screens are different than those identified by shRNA knockdown screens but usually identify the same pathways—thus these two types of genetic screens are complementary to each other.

Although most of the broad screens have been done in transformed cell lines, it is also now possible to perform such screens in primary cells, especially human T cells, by limiting the breadth of the screen.[54] Although there is some compromise in breadth, by avoiding the artifacts of screens in transformed cells that have been adapted to grow in a laboratory environment, often for decades, it is possible that understanding of the functioning of primary human blood cells will proceed more rapidly.

GENOME EDITING AS A THERAPEUTIC STRATEGY

Hematopoietic stem cell transplantation (HSCT), whether allogeneic or autologous, has been a validated curative approach to a wide variety of malignant and nonmalignant diseases since the late 1960s and early 1970s. In the past decade, the utility of hematopoietic cell therapy (HCT) to deliver genetically engineered T cells to fight cancer (notably chimeric antigen receptor [CAR] T cells) has also been established. Delivering ex vivo genome-edited hematopoietic stem and progenitor cells (HSPCs) or HCT (e.g., CAR-T cells) via HCT is building on this well-established therapeutic foundation and has the potential to make HSCT and HCT both safer and more effective.

However, two key principles need to be considered for ex vivo genome editing for HSCT- and HCT-based therapies. The first is that there is still a need to create niche space for the cell product prior to infusion. Currently for HSCT, this requires the use of myeloablative, genotoxic chemotherapy and, for HCT, pharmacologic depletion of T cells. The requirement for niche clearance creates toxicity and is presently needed for genome-edited cell therapies. It is possible in the future that genome editing could lead to approaches to make niche clearance safer and more effective. The second is the need to preserve potency and safety of the cell product after ex vivo manufacturing. Currently, genome editing requires cells to be maintained outside the body in an unnatural environment, and care must be taken to ensure that in the process of genome editing, the target cell population does not lose its biologic potency. For HSCs, for example, that would be the ability maintain the hematopoietic system for the lifetime of the patient by undergoing self-renewal and the ability to differentiate into all of the hematopoietic lineages.

EX VIVO MANUFACTURING OF THERAPEUTIC CELLS

Genome editing of cells is a quantitative process in that it is not enough simply to deliver a nuclease or a donor template, but instead they have to be delivered in sufficient quantities to achieve the desired on-target efficacy without delivering so much that it causes toxicity.[44] The relative indel formation is directly related to the amount of nuclease delivered to the cell until a plateau is reached. Similarly, the frequency of HDR is directly proportional to the amount of donor that is delivered until a plateau is reached. The primary counterforce in delivering sufficient quantities of genome editing reagents is that primary human cells have redundant and robust mechanisms to detect and inhibit the delivery of foreign nucleic acids (e.g., through the intracellular type I interferon innate immune response).[55] A secondary counterforce to efficient genome editing while maintaining cell potency is the cell's DNA damage response (DDR) to the creation of genomic DSBs and to the donor molecules themselves (in the case of HDR).[56] Thus, for successful therapeutic editing, sufficient quantities of genome editing reagents must be delivered to cells while minimizing the inhibitory responses to the process. Specifically, the delivery of genome editing reagents as naked DNA plasmids, a process that works well in transformed cell lines with damaged cytoplasmic DNA sensing systems, is not tolerated well by primary human cell such as HSPCs and T cells.

In addition to delivering the reagents without causing toxicity, for HDR-based editing, in which the cell needs to be in S/G_2 for HDR to occur, a manufacturing key is to develop ex vivo cell culture conditions that put the cells into cycle without compromising their long-term potency.

For meganucleases, ZFNs, and TALENs, the solution to ex vivo manufacturing is to deliver the nuclease as a highly purified messenger RNA (mRNA) with modifications to minimize detection of foreign RNA molecules, including the use pseudo-uridine, 5-methylcytosine, and HPLC purification to reduce double-stranded structures.

For CRISPR/Cas9, the current optimal delivery system is to deliver the nuclease as a ribonucleoprotein (RNP) complex. In this complex, purified Cas9 (which is easy to produce and stable) is mixed with a gRNA that is made synthetically with end-modifications to protect against degradation.[39] The gRNA is then complexed with Cas9 protein prior to delivery.

For both mRNA and RNP delivery, electroporation of cells to create pores through which the macromolecule enters is highly effective. Electroporation without contaminating DNA in the mix is surprisingly nontoxic to cells following optimization. Various electroporation devices that allow cell manufacturing of billions of cells are now available. Other methods that allow the macromolecules to enter cells may also be developed in the future. In all methods, the amount of nuclease macromolecule introduced needs to be titrated to achieve the desired ratio of efficacy to toxicity. One advantage of both mRNA and especially RNP delivery is the nuclease is present in the cell for only a short period (for Cas9 RNP for ~48 hours), which minimizes the possibility of creating breaks at off-target sites and decreases the cellular DDR. Using these nuclease delivery strategies, greater than 90% indels can be routinely achieved at the target site in primary human hematopoietic cells.

For HDR, the donor template must also be delivered in sufficient quantities. For HDR based on ssODNs, the purity of the ssODN is essential to enhance efficacy and minimize toxicity. Careful titrations of the amount of ssODN included are an important aspect of optimizing the manufacturing process. After optimization 30% to 50% HDR can be achieved in HSPCs using ssODN-based genome editing.[57]

For HDR using classic gene targeting donors and HR, recombinant adeno-associated virus serotype 6 (AAV6) has become the most effective method of delivering the donor molecule.[58–60] AAV6 has evolved to deliver its single-stranded DNA cargo to the nucleus of cells without being easily detected by cytoplasmic sensors of viral transduction.[55] The efficiency of AAV6 transduction of primary human HSPCs and T cells is enhanced by electroporation and is maximal if the AAV6 is applied to cells within 15 minutes of the electroporation.[61] As with the nuclease, ssODN, each AAV6 prep needs to be titered to achieve the desired efficacy and toxicity ratio. Using CRISPR/Cas9 RNP and AAV6, greater than 40% HDR can routinely achieved in HSPCs and up to 80% in T cells and certain loci in HSPCs. These frequencies of HDR are on allele basis, so a 40% HDR allele frequency results in between 55% to 70% HDR cell frequency depending on the ratio of monoallelic versus biallelic HDR.

Small molecules are increasingly being incorporated into the cell manufacturing process to improve efficacy and potency. These include small molecules to maintain stem cell potency,[62] inhibitors of the p53 response to minimize the DDR,[56] and small molecules that bias toward HDR rather than NHEJ for cells in situations where HDR is the desired editing event.[63,64]

THERAPEUTIC GENOME EDITING FOR HEMATOLOGIC DISEASES

Genome editing is being applied to a variety of diseases related to hematology and the blood system. The following are selected brief examples:

Sickle Cell Disease

Sickle cell disease is an autosomal recessive disease caused by a single point mutation in the *HBB* gene (see Chapters 42, 43). It is among the best understood genetic diseases, but currently the only curative therapy is allogeneic HSCT. However, the deep understanding of the pathophysiology of the disease has led to multiple exciting genome editing strategies to cure the disease. All currently involve the ex vivo manipulation of the patient's own HSPCs which are then transplanted back into the patient following myeloablative conditioning.

Fetal Hemoglobin Derepression

It is well documented that the severity of sickle cell disease is ameliorated by increasing the level of fetal Hb (HbF) in red blood cells because HbF acts as an antisickling Hb.[65] Upregulation of HbF is one of the major mechanisms of action for hydroxyurea, a disease-modifying small molecule.[66] Decades of research have uncovered the pathways by which HbF is downregulated at birth. One of the central proteins in this downregulation pathway is BCL11A, which is a transcription factor that suppresses gamma-globin expression.[67] There are several different genome editing approaches to inhibit the BCL11A repression (Fig. 5.4). The first is to inactivate an erythroid-specific enhancer for the BCL11A gene such that the protein is not expressed in the red cell lineage.[68,69] The inactivation is done by delivering a

Figure 5.4 DIFFERENT GENOME EDITING STRATEGIES FOR SICKLE CELL DISEASE.

CRISPR/Cas9 RNP complex to HSPCs that makes a break in the enhancer resulting in indels that inactivate the genetic element. Early clinical trial results show exciting promise in this approach. The small number of patients who have been treated are showing an elimination of vaso-occlusive pain crises and 50% to 60% HbF with 40% to 50% HbS in the red cell lineage in the first months following treatment.[70] This amount of HbF is predicted to prevent almost all sickling in the pancellular state, as the early results suggest it is. The long-term safety and efficacy are being evaluated.

The second is to inactivate BCL11A-binding sites in the gamma-globin gene cluster (mimicking naturally occurring hereditary persistence of fetal hemoglobin [HPFH] variants). In this strategy the CRISPR/Cas9 RNP is targeted to the BCL11A-binding sites in the gamma-globin cluster, thereby creating indels that prevent BCL11A from binding and repressing the gamma-globin genes.[71–73] Preclinical results show encouraging results in depepressing HbF using this direct globin cluster editing.

Direct Gene Correction

An alternative to the indirect approach of HbF derepression is to use HDR to directly convert the pathologic HbS allele to the nonpathologic HbA allele. Preclinical success using CRISPR/Cas9 RNP combined with either ssODN or AAV6 to template the correction has been achieved.[57,58,74] The frequency of allele correction has been 30% to 50% with ssODN and 40% to 80% with AAV6, resulting in 50% to 90% of cells having at least one allele corrected. The predicted threshold for clinical benefit based on mixed chimerism following allogeneic HSCT is that 5% to 20% cellular correction would have substantial, if not curative, clinical benefit. This increase in effect is because of the selective advantage of nonsickling red blood cells both in red blood cell development within the bone marrow and in the periphery.[75,76] Because CRISPR/Cas9 RNP is so active, the predominant genotype following the gene correction process is β thalassemiac trait. Thus patients with homozygous sickle cell disease (SS disease) may be converted to β thalassemia trait, a condition of mild anemia that millions of people around the world live healthy lives with and a condition that may even be more healthy than sickle cell trait. Clinical trials using both ssODNs and AAV6 began in 2022.

β-Thalassemia

β-Thalassemia is an autosomal recessive disease caused by mutations in the *HBB* gene that result in the production of insufficient HBB protein (see Chapter 41). Unlike sickle cell disease, the mutations that cause β-thalassemia are scattered throughout the *HBB* gene, including in the regulatory and pre-mRNA splicing elements. NHEJ and HDR approaches to β-thalassemia are being developed.

Fetal Hemoglobin Derepression

HbF upregulation, as described for sickle cell disease, is also an approach to treating β-thalassemia. By upregulating gamma-globin, the missing beta-globin is compensated for and unpaired alpha-globin chain precipitates would be prevented. The genome editing approaches for β-thalassemia to upregulate HbF are identical to those being used for sickle cell disease. The early clinical results for inactivating the erythroid specific enhancer of *BCL11A* show great promise with patients becoming transfusion independent within months of treatment and stable total Hb levels greater than 12, with essentially all of the Hb being HbF.[70] The long-term safety and efficacy of having such high levels of HbF are being evaluated, although patients with HPFH suggest that it is a relatively healthy condition.

Knocking HBB into HBA1

An HR approach to β-thalassemia has been described in which the *HBB* gene was knocked-into the *HBA1* gene without disrupting the *HBA2* gene (called “whole gene replacement”).[77] In this way, more HBB protein and less HBA protein is made, thus correcting the chain imbalance that is a key pathology in the disease. This can be considered a form of synthetic biology because the genome is being engineered such that one gene (HBB) is now being expressed instead of another gene (HBA1) through the HBA1 natural regulatory elements. In preclinical work, the ratio of beta-globin protein to alpha-globin protein was increased to the β-thalassemia trait level of 0.5 when red blood cells were evaluated from genome-edited HSPCs derived from β-thalassemia major patients. This expression level should mimic β-thalassemia trait.

Primary Immunodeficiency Diseases

There are hundreds of primary immunodeficiency diseases (PIDs) that affect the hematologic system. Unlike sickle cell disease, these are diseases in which disease-causing mutations are scattered throughout the gene. Unlike sickle cell disease and β-thalassemia, there are not indirect knockout approaches that can be used to compensate for the defective gene. A general "one size fits all" genome editing approach using HR has been developed for multiple PIDs (SCID-X1, WAS, IPEX, HIGM, CGD…).[78–83] In this strategy, a full wild-type cDNA is inserted into the early part of the gene (exon 1, intron 1, or exon 2, depending on the biology of the target gene regulation and the specifics of the strategy), thereby correcting downstream mutations. Using this strategy, more than 95% of disease-causing mutations can be addressed. In contrast to lentiviral-based gene therapy approaches, the cDNA is inserted into the natural locus and remains under the control of the endogenous regulatory elements. Because the strategy requires the targeted insertion of a full cDNA, the ssODN method will not work; gene targeting AAV6 donors have thus been used. The robustness of the CRISPR/Cas9 RNP and AAV6 donor platform is demonstrated by 30% to 50% targeted cDNA integration in HSPCs, including patient-derived HSPCs. This frequency of targeted integration would be predicted to be curative if achieved following transplantation because of the selective advantage of genetically corrected cells over mutated cells and because of the clinical potency of action of even a small percentage of functionally wild-type cells.

The improved effectiveness of the cDNA integration into the natural locus compared with lentiviral semirandom integration has been demonstrated for two genes. There was improved lineage-specific development (equivalent to wild-type development) in the natural killer (NK) lineage for severe combined immunodeficiency (SCID)-X1 and the platelet lineage for Wiskott-Aldrich syndrome using targeted integration compared with lentiviral insertion.[83] Moreover, for IPEX and HIGM (and other PIDs), lineage specific expression from endogenous regulation is essential for both safety and efficacy reasons.

Using the Blood System to Treat Nonhematologic Diseases (Metabolic Diseases)

The pharmacokinetic and pharmacodynamic properties of the hematologic system are powerful ways to deliver proteins to cure nonhematologic diseases. The system creates 200 billion new red blood cells, platelets, and neutrophils per day. Moreover, the cells from the hematologic compartment, especially macrophages, migrate into all of the tissues of the body, including the brain under stress. These properties give the blood system the potential to deliver therapeutic proteins to all tissues of the body.

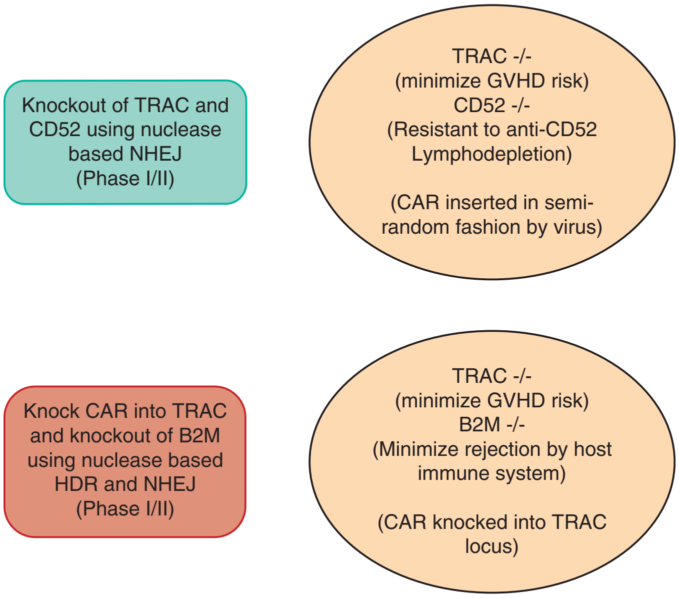
The potential of the hematologic system to cure nonhematologic diseases is demonstrated by the efficacy of allo-HSCT in treating metabolic diseases such as metachromatic leukodystrophy (MLD), mucopolysaccharidosis type I (MPS I), and Gaucher disease (among others). The limitation of allo-HSCT is the inability to quickly find immunologically matched donors to use, the immunologic complications of allo-HSCT including graft-versus-host disease, poor/slow immune reconstitution, and the sometimes-slow pharmacokinetics/pharmacodynamics that are not sufficient to halt a rapidly progressive disease. Genome editing autologous HSCs to express potent amounts of enzyme has the potential to solve many of the problems of allo-HSCT and expand applications for treating nonhematologic diseases. Successful proof-of-concept preclinical studies of MPS I, Gaucher, hemophilia B, and lysosomal acid lipase deficiency (causing Wolman disease) have all been published.[84–86]

Genome Editing of Immune Effector Cells for Safer and More Potent Cancer Therapies (CAR-T Cells)

CAR-T cells have shown significant efficacy and safety at treating hematologic malignancies, especially those expressing CD19 on the surface but also BCMA-expressing malignancies. The US Food and Drug Administration (FDA)–approved CAR-T-cell products are autologous T cells genetically engineered by lentiviral or retroviral vectors to express an anti-CD19 CAR. Genome editing is being applied to CAR-T-cell therapies in numerous different ways, but the two most advanced are: (1) to generate off-the-shelf, chemotherapy-resistant CAR-T cells and (2) to make CAR-T cells more potent by using targeted integration rather than retroviral or lentiviral semirandom insertion or by knocking out checkpoint inhibitors.

Off-the-Shelf CAR-T Cells

Autologous CAR-T-cell therapies, although effective, have challenges, including the inability to manufacture a potent cell product from patients who have been exposed to large amounts of prior lympholytic chemotherapy; the inability to manufacture a product in a timely fashion before the patient's clinical condition deteriorates; and the cost of making personalized cellular products. An "off-the-shelf" allogeneic product would solve many of these problems because they would be manufactured from people with healthy T cells; the products would be ready to go and premade for each patient, and multiple doses (tens to hundreds) could be manufactured at once, thereby decreasing cost. However, allogeneic CAR-T cells would cause graft-versus-host disease without modification, but genome editing, in a nuclease-agnostic manner, can create a population of allogeneic CAR-T cells by creating inactivating indels in the T-cell receptor alpha *(TRAC)* gene.[87] Moreover, genome editing can be used to create an allogeneic product that is resistant to lymphodepletion (e.g., creating anti-CD52 antibody–resistant cells by genome editing the *CD52* gene) (Fig. 5.5).[43] Early clinical trials have demonstrated that



Knockout of TRAC and CD52 using nuclease based NHEJ (Phase I/II)
TRAC -/- (minimize GVHD risk) CD52 -/- (Resistant to anti-CD52 Lymphodepletion)

genomes edited off-the-shelf do have efficacy but durability seems to be an issue.[88] More patients, as part of different trials, with longer follow-up will be informative. Even if the durability issue is not readily solved, if off-the-shelf CAR-T cells can create significant remissions, it would create the opportunity to build such cells into an HSCT program in which it is known that the efficacy of HSCT is higher when the patients undergo transplant with minimal residual disease.

Increasing Potency

The long-term remission rates following CAR-T-cell therapy remain in the 30% to 40% range for the FDA-approved products. Thus a goal is to improve the potency of these therapies to increase the long-term remission rate. Several genome editing approaches have been reported to increase the potency. One approach is to knock the CAR into the *TRAC* locus such that it is regulated as if it were a T-cell receptor. The proof-of-concept publication demonstrated that the knock-in CAR-T cells had decreased features of exhaustion, including in functional assays.[89] A second approach to improve potency is to use genome editing to knockout out PD-1 to mimic what is achieved pharmacologically by checkpoint blockade using inhibitors of the PD-1 pathway. Preliminary evidence of PD-1 knockout safety has been demonstrated, but the broader safety and efficacy of this genetic manipulation need to be determined.[90]

OPPORTUNITIES FOR GENOME EDITING IN VIVO

Although there are current partial solutions to the need for substantial room for improvement in ex vivo genome editing/autologous HSC transplantation, including in the patient conditioning process, the harvesting of the target cells, the manufacturing the cells, and the subsequent reintroduction of those cells into a patient, the need for all of these steps in and of itself suggests that if one could replace the ex vivo process with a "one-shot" in vivo genome editing drug, it could be ideal for many diseases. Absent simpler delivery platforms, widespread deployment of these therapies will be severely limited by the need to access sophisticated highly expert healthcare facilities capable of managing these complex processes safely.

In 2021, the first evidence of human in vivo genome editing was reported. In this work, a Cas9 mRNA and gRNA were complexed as part of a lipid nanoparticle (LNP) designed to be taken up by liver cells.[91] The target gene was *TTR*, a gene mutated in hereditary amyloidosis—a progressive multisystemic disease. The LNPs were infused intravenously into six patients without evidence of toxicity. Excitingly, there was short-term evidence of efficacy with reduction of protein levels of 86% in the blood at the highest LNP dose tested. Although the target gene was in the liver, the effect was to alter the concentration of a protein in the blood. Data beyond day 28 were not reported. This first safe use of in vivo Cas9-based editing is an important milestone in the field.

CHALLENGES TO IN VIVO EDITING OF HEMATOPOIETIC STEM CELLS

The challenges for in vivo editing of the hematologic system are currently even more difficult than those outlined for ex vivo editing (which is built on the established HSCT and HCT platforms). These challenges fall into two broad categories: (1) delivery and (2) immunogenicity.

Delivery

In vivo genome editing requires the development of a novel vector that would specifically target the cell of interest (whether HSCs or T cells or other blood cell) while not being taken up by the trillions of other cells (red blood cells, platelets, endothelial cells…) that the target cells live and coexist with in close proximity. In contrast to ex vivo editing where the target cell can be purified way from the competitor cells before editing, in an in vivo setting that would not possible. Furthermore, as discussed earlier, to achieve high frequencies of genome editing, whether through indels or HDR, requires a sufficient quantity of the genome editing reagent to enter the cell. A little gets only a little. Thus the new vector would not only have to selectively deliver to the target cell of interest but would also have to deliver the editing reagents in sufficient quantities to achieve therapeutic frequencies of editing. Finally, it should be noted that in terms of HDR, which requires cells to be cycling to be efficient, most HSCs are quiescent and so to harness HDR in vivo would require novel ways to put HSCs into cycle without compromising their long-term hematopoietic stem cell function.

Immunogenicity

The human immune system has been one of the barriers to safe and effective in vivo gene therapy, and one would anticipate the same to be true for in vivo gene editing. The first barrier is to avoid activating the intracellular innate immune response (type I interferon response) in all cells to which the novel vector delivered its cargo in vivo. The second barrier is to design a vector that does not profoundly activate the cellular innate immune response, such as macrophages and the reticuloendothelial system. The third barrier is the adaptive immune response to the genome editing reagents and vector. All of the nuclease systems involve parts that are foreign. For CRISPR/Cas9, the Cas9 protein has been demonstrated to generate an adaptive immune response, even in naïve animals.[92,93] Therefore, for in vivo editing, one would need enough nuclease to get therapeutic levels of editing but have it disappear before the adaptive immune response recognized the foreign protein and eliminated the cells still expressing it (like a virus). Moreover, most healthy adults already have a preexisting immune response to both *Staphylococcus aureus* and *S. pyogenes* Cas9.[94–97] For in vivo AAV gene therapy, patients who have even very low titers of preexisting antibodies to the AAV serotype are excluded from treatment because the preexisting immunity diminishes efficacy and might create systemic inflammation, toxicity, and death.

Proponents of in vivo editing also argue that it would be cheaper than an ex vivo process, but this assumption has not been pressure tested. A simple counter example is that the current most expensive drug in the world is an in vivo AAV-based gene therapy for spinal muscular atrophy, not an ex vivo HSPC gene therapy. In addition, the amount of AAV (the current best vector) for systemic in vivo delivery of nucleic acids needed for one patient for in vivo editing would be sufficient for thousands, if not tens of thousands, of patients using an ex vivo approach.

Nonetheless, ex vivo editing of HSCs at levels that might cure hematologic diseases was also considered an unrealistic dream not even two decades ago, so the creativity, ambition, and motivation of a large number of researchers might, over the next decades, discover solutions to the known challenges described earlier. We can anticipate that solving currently unknown barriers to in vivo editing will have to, and will, occur.

HERITABLE GENOME EDITING

The concept of genetically engineering the genome to pass along changes to future generations has been a serious topic of study over decades for a wide range of people, including the subject of movies and books. However, until the development of the CRISPR/Cas9 system, the specificity and efficacy of any genetic engineering system was never even close to reaching levels to take the discussion beyond theory and speculation. The efficiency of the CRISPR/Cas9 system in nonhuman zygotes to create genetically engineered animal models took the possibility of doing the same in humans beyond speculation into the realm of possible. It has prompted a global discussion of the technical, ethical, societal, and governance aspects of the potential of heritable human editing. These discussions are ongoing and international in scope. The broad consensus is that, because there remains a lack of clarity around technical, ethical, societal, and governance issues, creating a human pregnancy from genome-edited zygotes, genome-edited gametes, or genome-edited germ cell precursors should not be permitted. Anyone proceeding with such an activity at this time demonstrates profound hubris and pathologic disrespect for humanity and should be considered a rogue actor and treated accordingly as a criminal.

Even if a broad positive consensus on technical, ethical, societal, and governance issues were one day attained, the need for heritable genome editing to prevent a child born with a devastating disease is remarkably small. The need is small because of the already available alternatives, especially the use of in vitro fertilization, preimplantation genetic diagnosis to identify zygotes who wound not carry the disease, and subsequent implantation of only those zygotes not at risk in vitro fertilization [IVF]/pre-implantation genetic diagnosis [PGD]. The number of couples for whom in vitro fertilization [IVF]/pre-implantation genetic diagnosis [PGD] would not be a way to have a healthy child is nonzero but continues to be almost academic in nature. The need will become even smaller as effective curative somatic cell therapies are developed over the coming years—therapies that the FDA predicts will be approved in the near future at tens or more per year. The paradox that by curing more patients while maintaining fertility we might actually increase the number of patients who would then need to undergo the same postnatal curative therapy. This then becomes an argument about economics as well as ethics.

CHAPTER 6

SIGNALING TRANSDUCTION AND METABOLOMICS

Pere Puigserver

Hematopoiesis is a cellular process in which self-renewing stem progenitor cells differentiate into mature blood cells, which carry out specific biologic functions. These functions include oxygen delivery, clot formation, and immune responses, including defense of the host from infection and inflammation. Homeostasis of the whole hematopoietic system in vivo requires a tight control of systems and networks governing proliferation, cell fate, cell death, differentiation, cell–cell interaction, and migration. Imbalance in or dysregulation of these processes results in pathologic alterations. For example, uncontrolled cell proliferation is a signature of leukemias, and defective lymphocyte differentiation can lead to immunodeficiency, or tumor immune responses will determine cancer progression. A better understanding at the molecular level of these biologic events will help to identify new therapeutic targets for the design of better drugs to treat hematologic diseases.

Because of the diversity in cellular types and their respective, specific biologic functions, hematopoietic cells respond to a broad array of extrinsic and intrinsic signals transduced through signaling and metabolic pathways. It is therefore important to recognize that these pathways serve to ultimately define a specific functional response and activity in each cell type. These regulatory signals (Table 6.1) can be general, such as growth factors (e.g., insulin growth factor [IGF], fibroblast growth factor [FGF]) or amino acids that control proliferation, or highly specific, such as the antigen signaling response in immune cells or 2,3-diphosphoglycerate in erythrocytes. Importantly, the action of these signals, as well as their integration inside the cell, is needed to accomplish a specific cellular task (either a physiologic or cellular fate decision). Moreover, as will be discussed later in this chapter, these signals also serve to tightly control metabolites in hematopoietic cells, defining a metabolomic profiles involved in processes such as anaerobic glycolysis for energy generation in red blood cells (RBCs) or immune and inflammatory responses in tumors.

Extrinsic cellular signals, often polypeptides, are recognized by plasma membrane receptors that trigger a phosphorylation cascade (using tyrosine and/or serine/threonine residues) that propagates through the cytoplasm and cellular organelles, including the nucleus. Thus the sequential activation of this cascade occurs in a temporal and spatial manner to define the specific biologic response. In general, there are two types of signals (Fig. 6.1): (1) signals that transduce immediate- or short-term biologic outputs without changes in gene expression, and (2) signals that transduce medium- and long-term biologic outputs with changes in gene expression. In the first case, for example, chemoattractants induce the phosphatidylinositol 3-kinase (PI3K) and Cdc42 pathways to rapidly establish neutrophil polarity. One example in the second case is the signaling transduced through Frizzled (Fz) receptors and the transcription factor T cell–specific transcription factor (TCF)-1 necessary for T-cell development. Another example is the programmed death-1 (PD-1) ligand in tumor cells that binds to the PD-1 receptor in T cells controlling the immune response. In these cases, the signals transduced are amplified through a series of physical interactions and chemical modifications on proteins, the most common being phosphorylation, but others such as ubiquitination, acetylation, and sumoylation also play important roles.

In this chapter, a general survey of the different key signaling and changes in energy metabolism that operate in hematopoietic cells will be reviewed. The goal is to provide the molecular basis by which signals are transduced and control fundamental cellular processes, including energy metabolism, in different lineages of the hematopoietic system.

SIGNALING TRANSDUCTION

Hematopoietic cells use general signaling transduction pathways that are common to most human cell types. The specificity in these signaling transduction pathways is often established at the beginning of the pathway's activation (e.g., by specific antigen-binding or ligand–membrane receptor complexes) (Table 6.2) and at downstream targets, including transcription of the specific genes that will serve to define a particular biologic process and response (see Fig. 6.1). Here we will review these general signaling transduction pathways, illustrating some of the specific components of hematopoietic cells.

Receptor Tyrosine Kinases, Phosphoinosite-3-Kinase, and Mitogen-Activated Protein Kinase Pathways

Receptor Tyrosine Kinases

Receptor tyrosine kinases (RTKs) are enzyme-linked receptors localized at the plasma membrane containing an extracellular ligand-binding domain, a transmembrane domain, and an intracellular protein–tyrosine kinase domain. In general, the ligands for RTKs are proteins such as IGF, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and FGF. Ephrins that bind to Eph receptors also form a large subset of RTK ligands. Colony-stimulating factor 1 (CSF-1), which is important for macrophage function, is another example of an RTK ligand. RTKs can function as monomers or multimeric subunits assembled at the plasma membrane that, upon ligand binding, cause oligomerization or conformational changes followed by tyrosine (trans)-phosphorylation in the kinase activation loop. Activation of RTKs results in phosphorylation of additional sites in the cytoplasmic part of the receptor, leading to docking of protein substrates, which initiates the intracellular signaling cascade. These substrates bind to RTK-phosphorylated tyrosines through Src homology-2 (SH2) domain or phosphotyrosine-binding (PTB) domains. Examples of these types of proteins are insulin receptor substrates or the p85 regulatory subunit of PI3K. RTKs recruit, assemble, and phosphorylate different proteins, including adaptors and enzymes.

There are mechanisms to terminate ligand-induced RTK activity through cellular processes including receptor-mediated endocytosis and/or through a family of regulated protein tyrosine phosphatases (PTPs), some of which are transmembrane and have extracellular domains, suggesting the possibility of ligand-mediated regulation. Interestingly, there is also intracellular regulation of PTPs through negative-feedback loops to attenuate the signal or direct control through reactive oxygen species (ROS) (see later discussion).

Phosphatidylinositol 3-Kinase Pathway

One of the key signaling components associated with RTKs is the PI3K signaling transduction pathway. This pathway is also activated by cytokine receptors and G protein–coupled receptors (GPCRs). Among the many functions of this pathway in hematopoietic cells, the interleukin-3 (IL-3)-dependent survival of these cells largely depends on activation of the PI3K pathway. PI3K is a heterodimeric complex formed of a regulatory and a catalytic subunit. The regulatory protein subunits are encoded by isoforms (which include p85α and p85β) that contain SH3-binding domains that mediate binding to activated RTKs. This binding allows additional recruitment and activation of the PI3K catalytic subunits (p110α, p110β, and p110*). At the plasma membrane, activated PI3K phosphorylates phosphoinosite-2 (PIP2) at position 3 of the inositol to produce PIP3. In addition, Ras, a small GTP-binding protein and potent oncogene, also activates PI3K. PTEN, an important lipid phosphatase and tumor suppressor, dephosphorylates PIP3, counteracting PI3K

TABLE 6.1 **Signals in the Hematopoietic System**

Types of Ligands	Examples
Peptide or Protein	
Soluble	Growth factors or cytokine
ECM	Fibronectin, collagen
Cell surface bound	ICAM, Kit ligand
Small organics	Thyroid hormone
Nucleotides	
Soluble	ADP
DNA	Double-strand breaks
Lipids	Eicosanoids, LPS
Gases	H_2O_2, nitric oxide[a]

[a] Function in hematopoietic system not well defined.

ADP, Adenosine diphosphate; *ECM*, extracellular matrix; *ICAM*, intercellular adhesion molecule; *LPA*, lipopolysaccharide.

TABLE 6.2 **Receptors in the Hematopoietic System**

Types of Receptors	Examples	Types of Ligands
RTK	Insulin, Kit, Fms	Kit ligand, M-CSF
RSK	TGF-β receptors	Activin, BMPs, TGF-β
GPCR	Thrombin receptor, CXC, CC receptors	Thrombin chemokines
PTK-associated	Cytokine receptors	Epo, interleukins,
MIRR	BCR/TCR/FcR	IFN peptide/MHC, Fc domains
TNF family	Fas, TNFR, CD40	Fas, TNF, CD40L
Notch	Notch	Delta-serrate-LAG-2
Frizzled family	Wnt receptors	Wnts
Toll receptors	TLR1-10	Bacterial DNA, LPS
RPTP	CD45	Unknown
Nuclear receptors	AR, RAR	Testosterone, retinoids

Figure 6.1 EXAMPLES OF LIGANDS AND RECEPTORS THAT TRANSDUCE BIOLOGIC RESPONSES. Signals can originate from fixed ligands (e.g., the extracellular matrix [ECM]) or soluble ligands that are not membrane permeable and bind to extracellular regions of transmembrane receptors. Membrane-permeable ligands bind to intracellular receptors, such as the nuclear receptor family. Signals can also originate from within the cell, such as increases in ROS levels. These signals cause short-term biologic outputs without changes in gene expression, or transduce medium- and long-term biologic outputs with changes in gene expression. *ECM*, Extracellular matrix; *ROS*, reactive oxygen species.

and decreasing the intensity of the pathway. Accumulation of PIP3 at the plasma membrane recruits several pleckstrin homology domain (PHD)-containing proteins, among them PDK and AKT serine/threonine kinases, which are key components in transducing PI3K signaling. Activated AKTs target different protein substrates for initiation of a biologic response. For example, the Bad protein, phospho-Bad, does not bind Bcl-2 and functions as an antiapoptotic mechanism, promoting cell survival. Other key targets of AKTs are the Forkhead transcription factors (FoxOs) (Fig. 6.2). When phosphorylated by AKT, phospho-FoxOs are sequestered and inactive in the cytoplasm through direct binding to 14-3-3 proteins. In contrast, dephosphorylated FoxOs activate gene expression associated with stress resistance and cell growth arrest. Another major component downstream of Akt is mammalian target of rapamycin (mTOR, a kinase that belongs to the PI3K-related protein kinase family), which is involved in metabolism, growth, and proliferation. Akt phosphorylates TSC2, which forms a complex with TSC1, decreasing its GTPase-activating protein (GAP) activity for the small GTPase Rheb; as a consequence, the increases in GTP-Rheb activate mTORC1 (one of the mTOR complexes). Among the key downstream targets of mTOR are S6K and 4EBP1, which control protein translation. mTOR can also be activated independently of RTKs through nutrients including branched chain amino acids. mTORC1 forms an amino acid–sensing complex at the lysosomal membranes called the pentameric Ragulator complex that contains Rags, small GTPases that are controlled by the GATOR complex. Interestingly, mTORC1 inhibitors such as rapamycin are used as immunosuppressors in organ transplantation.

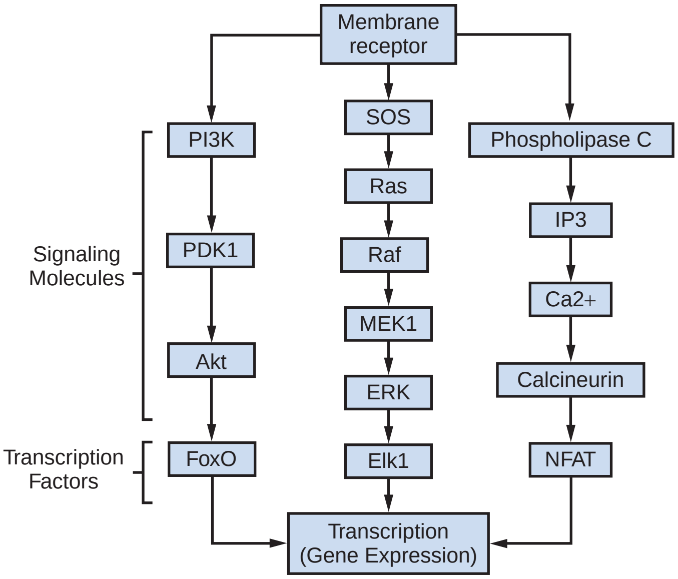

Figure 6.2 EXAMPLES OF SIGNALING/TRANSCRIPTIONAL PATHWAYS PROGRAMMING GENE EXPRESSION. Proteins involved in gene expression are a common target of many signaling pathways, and receptors often stimulate multiple pathways that can regulate common and distinct transcription factors. In the examples shown here, production of PtdIns-3,4,5-P3 by PI3K leads to the activation of the serine/threonine kinase Akt. Akt phosphorylates and inactivates FoxO transcription factors. Ras is activated by the guanine nucleotide exchange factor SOS. Ras activation initiates a cascade of serine/threonine kinases activity: Ras activates Raf, Raf phosphorylates and activates Mek1, and Mek1 phosphorylates and activates ERK. Phosphorylation of the transcription factor Elk1 by ERK activates gene expression. Increased intracellular calcium is also a common signaling event. Activation of phospholipase C leads to hydrolysis of PtdIns-4,5-P2 and production of IP3. IP3 binds to its receptor, leading to intracellular calcium release and then extracellular calcium influx. Calcium activates the serine phosphatase calcineurin, which dephosphorylates NFAT proteins, allowing them to enter the nucleus and stimulate transcription. *FoxO*, Forkhead transcription factors; *IP3*, inositol triphosphate; *NFAT*, nuclear factor of activated T cells; *PI3K*, phosphatidylinositol 3-kinase; *SOS*, Son of Sevenless.

MAPK/ERK Pathway

Activated RTKs recruit docking proteins, such as Grb2 and SOS, that allow binding of GTP to Ras to become active and trigger a kinase signaling cascade. Ras activates RAF kinase that, in turn, triggers a series of MEKs, which finally activate MAPK or EEK kinases. ERK phosphorylates many proteins involved in cell growth, including ribosomal S6K, which is involved in protein translation, and AP-1 and c-myc transcription factors, which increase many different cell cycle and antiapoptotic-related genes (see Fig. 6.2). Other MAPKs include the stress-activated kinases JNK and p38. Constitutive MAPK in hematopoietic stem cells is known to induce myeloproliferative disorders.

The Transforming Growth Factor-β Pathway

The transforming growth factor (TGF)-β family of cytokines contains two subfamilies: the TGF-β/Activin/Nodal and the bone morphogenetic protein (BMP)/growth and differentiation factor (GDF)/müllerian-inhibiting substance (MIS) subfamilies. At the plasma membrane, TGF-β ligands bind with high affinity to the ectodomain of type II receptors, which then recruit type I receptors. This forms a large ligand-receptor complex involving a ligand dimer and four receptor subunits. Upon ligand binding, the type II receptor phosphorylates multiple serine and threonine residues in the cytoplasmic GS-rich region of the type I receptor, leading to its activation. The phosphorylated TGF-β type I receptor binds to and phosphorylates Smad2 and Smad3 transcription factors, which are critical mediators of TGF-β signaling and function. Upon phosphorylation, Smad proteins translocate to the nucleus to activate gene expression through binding to specific DNA-binding sites. There are several mechanisms to terminate Smad activation, which include proteasomal degradation and dephosphorylation. TGF-β-1 has been shown to be associated with active centers of hematopoiesis and lymphopoiesis in the developing fetus.

Signaling Through Receptors Associated With Protein-Tyrosine Kinases

Here, three different types of receptors and their signaling are included: (1) cytokine receptors, (2) multichain immune recognition receptors, and (3) integrin receptors.

Cytokine Receptors and Janus-Activated Kinase Signaling

The cytokine receptor superfamily mediates many of the central specific responses in hematopoietic cells. Ligands for these receptors include interleukins, thrombopoietin, erythropoietin, and so on. Cytokine receptors possess a conserved extracellular region (cytokine receptor homology domain [CDH]) and several structural modules, including extracellular immunoglobulin or fibronectin type III–like domains, transmembrane domains, and intracellular homology regions. Based on the divergence of the CHD, cytokine receptors are classified into two classes: class I and class II receptors. Class I receptors contain two pairs of cysteines linked through a disulfide bond and a C-terminal WSXWS motif within the CHD. This class is further subdivided into three families: IL-2R, IL-3R, and IL-6R. All three receptor families share similar receptor chains. The class I cytokine receptors are formed by one chain containing two motifs (Box 1 and Box 2), which transduce signaling through binding to Janus-activated kinase (JAK; see later discussion). Also included in this class are the homomeric receptors that form homodimers upon ligand binding. Examples of these receptors include the erythropoietin, thrombopoietin, prolactin, and growth hormone receptors. Class II receptors also have two pairs of cysteines but lack the WSXWS motif found in class I receptors. There are pools of 12 class II receptor chains that are capable of forming a total of 10 receptor complexes. This class is functionally divided into antiviral receptors (three receptor complexes that bind interferons) and non-antiviral receptors, which bind to several interleukins such as IL-10 and IL-20.

The oligomeric structures of cytokine receptors are complex and cannot be generalized. Cytokine binding often induces oligomerization, which activates protein tyrosine kinases in the JAK family that are constitutively associated with the Box 1 and 2 motifs of the cytokine receptor. Oligomerization brings JAKs in close enough proximity to trans phosphorylate on Tyr residues. This activates JAK, which results in the phosphorylation of other cytokine receptors as well as other substrate proteins. Among these substrates, the signal transducer and activator of transcription (STAT) family of transcription factors are pivotal to JAK-mediated cytokine signaling. STATs are phosphorylated on Tyr residues by JAKs upon cytokine binding to the receptor. Phospho-STATs homodimerize or heterodimerize and translocate to the nucleus to activate gene expression. STATs are also phosphorylated on a serine residue via MAPK, which serves to strengthen the intensity of the signal. As part of the cytokine signaling attenuation, STATs induce genes encoding for suppressors of cytokine signaling (SOCS) proteins, which bind to phosphotyrosine residues of the cytokine receptor and JAK through SH2-binding domains.

JAK inhibitors, based on their ability to block cytokine signaling, are used in allergic and rheumatoid arthritis disease therapy.

Multichain Immune Recognition Receptors

This family of receptors includes antigen receptors in B and T lymphocytes, activating receptors in natural killer (NK) cells, and immunoglobulin E (IgE) and Fc receptors. This class of receptors contains different integral membrane subunits that bind the ligand at the cell surface and transduce the signal. Ligand binding induces oligomerization of receptor subunits that contain immunoreceptor tyrosine-based activation motifs (ITAMs) within their cytoplasmic domains. These domains become phosphorylated on tyrosine residues upon receptor activation. These phosphotyrosines are involved in activation of a series of protein tyrosine kinases containing SH2 domains that include Src (Src family kinase [SFK]), Syk (Syk or ZAP-70), and Tec (Btk, Itk, Rlk), which mediate immune signaling through downstream pathways that include MAPK, calcium signaling, and nuclear factor (NF)-κB, among others. In Tec kinases, additional downstream targets include enzymes such as phospholipase C γ (PLCγ). The precise mechanism of this activation is not completely understood, and in some cases, such as T-cell receptors, a PTP (CD45, which counteracts the action of SFKs) is regulated upon ligand binding.

The activities of some of these receptors are the basis of immunotherapy in cancer. For example, PD-1 mediates tumor-induced immunosuppression. Cancer cells express the PD-1 ligand, which activates the PD-1 receptor present in tumor-infiltrated lymphocytes, suppressing the immune response. Signaling transduction through the PD-1 receptor involves tyrosine-depending binding to SHIP1/2 phosphatases. Blockade of PD-1 activation with monoclonal antibodies has been successful in treating several human tumors such as melanoma. Mechanistically, T cells are activated through the T-cell receptor upon binding of major histocompatibility complex (MHC) plus peptides on an antigen-presenting cell (APC; in this case in the tumor cell), and binding of APC CD80/86 to T cell CD28. Activation of the T-cell receptor increases expression of PD-1 to suppress the immune/inflammatory response. Cancer cells activate this pathway, upregulating the PD-1 ligand to promote survival and suppress the immune-mediated death of tumor cells.

Integrin Signaling

Integrin receptors are involved in cell adhesion, migration, survival, and growth. This signaling is central in hematopoietic cell function (e.g., at places of inflammation or infection, where integrins trigger a cascade by which leukocytes exit the vasculature). Interestingly, these receptors signal bidirectionally through the plasma membrane in pathways referred to as *inside-out* and *outside-in signaling*. Integrins are a class of receptors that comprise heterodimeric type I transmembrane proteins consisting of α and β subunits. These subunits contain a large extracellular domain, a single transmembrane domain, and a short cytoplasmic tail. There are 18 α and 8 β subunits that are associated and form 24 different integrins with different affinities for ligands. Most of the ligands are extracellular matrix (ECM) proteins containing one of the two motifs: arginine-glycine-aspartate (RGD) or leucine-aspartate-valine (LDV). Examples of integrin ligands are ICAM-1, which is present at the plasma membrane of APCs and binds to the integrin receptor LFA-1 to promote cell-cell adhesion.

Ligand binding to the extracellular domain induces clustering of integrins, allowing separation of the different subunits cytoplasmic portions forming interactions with cytoskeleton proteins involved in actin polymerization (outside-in signaling). Signals arising from the cellular interior, including phosphorylation, can also separate these cytoplasmic domains and can affect ligand binding (inside-out). Ligand binding to integrin receptors also signals to protein tyrosine kinases such as the SFKs and focal adhesion kinase (Fak). This part of the signaling is not completely understood but appears to involve a domain in the β-integrin tail (NPXY motif) that binds talin, which in turn recruits paxillin that binds Fak, which, once activated, phosphorylates SFKs to mediate integrin response. Paxilin-independent integrin signaling that also mediates survival and migration have also been observed in intracellular endosomal compartments.

Tumor Necrosis Factor Receptors and Signaling

Tumor necrosis factor receptors (TNFRs) influence inflammation, innate immunity, lymphoid organization, and T-cell responses. There are approximately 19 different ligands for TNFRs that mediate cellular responses through 29 TNFRs. TNFRs are a family of single membrane–spanning proteins that contain an extracellular tumor necrosis factor (TNF)-binding region and a cytoplasmic tail. As in the case of other cytokine receptors, ligand binding causes oligomerization and the formation of a mature receptor complex that is required to transduce the signal. TNFRs fall into three classes: (1) death domain (DD)-containing receptors (fatty acid synthase [FAS], TNFR1, and DR3), which activate the caspase cascade via the DD-initiating extrinsic apoptotic pathway; (2) decoy receptors, which lack a cytoplasmic tail and therefore cannot transmit the signal, making these receptors ligand sequesters; and (3) TNFR-associated factor (TRAF) receptors such as TNFR2, which lack the DD-recruiting TRAF proteins. In general, TRAFs are associated with either proapoptotic or survival pathways through activation of the NF-κB family of transcription factors and MAPK signaling (ERK, JNK, and p38). TRAFs activate NF-κB through ubiquitin-mediated degradation of their inhibitor IκBα, which retains NF-κB inactive in the cytoplasm. This process is initiated by phosphorylation of IκBα by the IκBα kinase (IKK) complex, mainly by the IKK-β catalytic subunit, and requires a regulatory subunit (also known as NEMO). Upstream of IKKs are other kinases including NF-κB-inducing kinase (NIK), which binds to TRAFs. Nuclear-activated NF-κB modulates gene expression, which mediates TNF biologic responses.

Toll-Like Receptors and Signaling

Toll-like receptors (TLRs) play essential roles in the innate immune response. Ten TLRs have been identified and can be grouped into two classes based on their extracellular domain: (1) TLRs with leucine-rich repeats and (2) TLRs with immunoglobulin domains. The ligands for TLRs are diverse and include the different constituent components of the microorganism, such as lipopolysaccharides (LPSs) and heat shock proteins (which bind to TLR2 and TLR4). Host defense against microorganisms mainly relies on signals originating from the TIR (Toll/IL-1) intracellular domain (a domain present in TLRs and IL-1Rs). The TLR signaling pathway is similar to the one triggered by the IL-1R. Ligand binding induces TLR multimeric receptor complexes, recruiting adaptor proteins such as MyD88, which contains a TIR domain and a DD, that in turn binds to the IL-1R–associated kinase (IRAK). IRAK is activated by phosphorylation and then associates with TRAF6, leading to activation of mainly two different pathways, JNK and NF-κB to activate the innate immune response, including release of inflammatory cytokines.

Wnt Signaling

Wnt proteins are lipid-modified, secreted proteins of approximately 400 amino acids that bind to Wnt cell surface transmembrane receptors, Fz, to initiate the canonical Wnt signaling transduction pathway. At the plasma membrane, binding of Wnt ligands to Fz receptors connect through direct binding to several intracellular proteins including Disheveled (Dsh), glycogen synthase kinase-3β (GSK3β), Axin, and adenomatous polyposis coli tumor suppressor (APC), inhibiting proteasome-mediated degradation of the transcriptional protein β-catenin. This degradation is regulated through GSK3β-mediated phosphorylation of β-catenin. As a consequence, β-catenin accumulates in the cytoplasm and translocates to the nucleus, where it interacts with transcription factors such as lymphoid enhancer-binding factor 1 (LEF)/TCF to modulate gene expression.

Notch Signaling

Notch ligands are plasma single-pass transmembrane proteins named Delta-like and Jagged. Thus cells expressing the ligands are adjacent to cells expressing the Notch receptors, which are also transmembrane proteins. The Notch receptor interacts with a Notch ligand on a contacting cell; this interaction produces Notch receptor cleavage, which releases the Notch intracellular domain (NICD). The NICD translocates to the nucleus, where it binds to several DNA-binding proteins including CBF1/Suppressor of Hairless/LAG-1 (CSL). As a result of this interaction between NICD and CSL, changes in Notch target genes occur. In contrast to the other signaling pathways discussed in this chapter that mainly function through phosphorylation, there is no amplification from the initial Notch ligand binding to the receptor. Moreover, this core pathway is modulated through auxiliary proteins that influence the response to the Notch ligand. Among these proteins are acute myeloid leukemia 1 (AML1), discoidin domain receptor family (DDR1), NECD, Notch extracellular domain, and CBF1-interacting protein.

Hedgehog Signaling

Hedgehog (Hh) signaling is a ligand-dependent signaling pathway. There are three different protein ligands—Sonic, Desert, and Indian—that are secreted and produce an N-terminal active fragment. Indian appears to be highly expressed in hematopoietic tissue. These ligands bind to Patch transmembrane receptors and are internalized, and Smoothened (a GPCR member) translocates to the plasma membrane of the primary cilium and promotes activation of the Gli family of zinc finger transcription factors. Hh targets include genes involved in differentiation, apoptosis, and the cell cycle. Abnormal activation of Hh signaling occurs in hematologic malignancies and maintains stem cell expansion. Because these cells are resistant to conventional chemotherapy, Hh antagonism is considered a plausible target in these malignancies.

Nuclear Hormone Receptor Superfamily

Nuclear hormones include steroid hormones (sex hormones, glucocorticoids, and mineralocorticoids), sterol hormones (vitamin D and its derivatives), thyroid hormones, and retinoids. These hormones are lipophilic and need carrier proteins to be transported in the blood. Due to this hydrophobicity, they can diffuse across the plasma membrane to reach the receptor proteins inside the cells, either in the cytoplasm or in the nucleus. These receptors are called the nuclear hormone receptor (NHR) superfamily. What distinguishes this receptor family from those discussed previously is their ability to directly bind to DNA and coordinate gene expression, which effectively makes them a form of transcription factor. NHRs contain a central DNA-binding domain, which targets the receptor to DNA sequences known as hormone response elements. In addition, the C-terminal part of the receptor contains a ligand-binding domain where the ligand or hormone binds. Upon ligand binding, NHRs control the expression of diverse sets of genes related to the hormonal response. Based on the types of ligands that they can bind, NHRs can be grouped into four classes: (1) steroid receptors, which include receptors for glucocorticoids, mineralocorticoids, progesterone, androgen, and estrogen; (2) retinoid X receptor heterodimers, such as thyroid receptor, retinoic acid receptor, vitamin D receptor, and peroxisome proliferator-activated receptors; (3) dimeric orphan receptors, such as COUPTF or HNF4; and (4) monomeric orphan receptors, such as NGFI. The cognate ligands for orphan receptors have yet to be identified.

G Protein–Coupled Receptor and Chemokine Signaling

G Protein–Coupled Receptor Signaling

The GPCR superfamily comprises a large collection of proteins, with approximately 2000 annotated genes in the human genome (~10% of the entire genome). GPCRs are involved in a large array of physiologic functions, including platelet aggregation and leukocyte chemotaxis. GPCRs are single polypeptides with seven-pass transmembrane domains containing both cytoplasmic and extracellular regions. Ligands for GPCRs are very diverse and include proteins or peptides, amino acids, lipids, and nucleotides that bind at the cell surface where GPCRs are localized. In spite of its vast size and variety of activational ligands, the GPCR superfamily relies upon three main intracellular signaling cascades for communicating receptor activation: the cyclic adenosine monophosphate (cAMP)/protein kinase A (PKA), the phosphatidylinositol/phospholipase C, and the Rho GTPase-based cascades.

GPCRs are coupled to a heterotrimeric G protein formed from three unique subunits (α, β, and γ) that are membrane bound. The G-α subunit contains a GTPase domain, which is capable of hydrolyzing GTP to GDP. When bound to GDP, the complex is functionally inactive, with the G-α subunit remaining tightly associated with the other subunits of the GPCR complex. Upon ligand binding to the GPCR, structural conformational changes produce the release of GDP from the heterotrimeric complex, allowing GTP to bind to the G-α subunit. In this GTP-bound form, the G-α subunit dissociates from the G-β and G-γ subunits with which it interacts. The G-α subunit then proceeds to interact with its downstream cognate targets to affect a particular signal response, depending upon the GPCR and the specific G-α subunit isoform. Among these second-messenger effectors are the cAMP/PKA pathway, ion channels, Rho GTPase, MAPK, PI3K, and inositol-3-phosphate/diacylglycerol (InsP3/DAG) pathways. In the case of the cAMP pathway, adenylate cyclase is downstream of different GPCRs (e.g., adrenergic receptors) and is activated by GTP-bound G-α. Adenylate cyclase converts ATP to cAMP, a freely diffusible second-messenger molecule. A key effector of intracellular cAMP is PKA, an inactive tetrameric protein complex consisting of two regulatory and two catalytic subunits. Binding of cAMP to the regulatory subunits causes release and activation of the catalytic subunits, which phosphorylate different cellular targets. Among them are the transcription factor cAMP-responsive element (CREB) and several ion channels. In addition to adenylate cyclase, there are other common effectors downstream of GPCRs, such as phospholipase C, a plasma membrane–bound enzyme that cleaves phosphatidyl inositol (PIP2) into two products and messengers: inositol triphosphate (IP3) and DAG. IP3 can diffuse through the cytoplasm and bind receptors in the endoplasmic reticulum (ER), resulting in calcium release to the cytoplasm. Importantly, calcium propagates the signaling cascade through different proteins such as calcineurin and nuclear factor of activated T cells (NFAT) transcription factors (see Fig. 6.2), which are involved in, for example, IL-2 gene expression. DAG at the plasma membrane binds and activates, in conjunction with calcium, protein kinase C (PKC), which will phosphorylate other downstream targets. Rho guanine nucleotide exchange factor (RhoGEF) is also a target for some G-α subunits. Binding of the G-α subunit to Rho allosterically activates it, causing GTP to be preferentially bound. This, in turn, allows RhoGEFs to activate Rho kinase, which is involved in the cytoskeletal reorganization necessary for changes in cell shape and motility.

Chemokine Signaling

Chemokines mediate cell migration in immune surveillance, inflammation, and development. There are nearly 50 human chemokines divided into four families (CXC, CC, C, and CX3C) on the basis of the pattern of internal cysteine residues; thus C stands for cysteine and X/X3, one or three noncysteine amino acids. Expression of some of these chemokines is induced by inflammatory signals such as TNF-α, interferon-γ, trauma, or microbial infection. There are approximately 20 signaling chemokine receptors, and they are all GPCR receptors; thus the chemokine acts as a ligand, and activation of the chemokine receptor follows the principles described previously. The major downstream effectors are cAMP and calcium messengers. Interestingly, some of the chemokine receptors also bind human immunodeficiency virus (HIV) viral proteins.

cGAS–cGAMP–STING Signaling Pathway

The presence of cytoplasmic DNA, through infection or DNA damage, activates innate immune responses. A mechanism of sensing this misplaced DNA is through the cGAS–cGAMP–STING signaling pathway. Cytosolic DNA binds and activates the cGAS enzyme (cGAMP synthase), which produces a second messenger, the cyclic dinucleotide 2′,3′-cGAMP, using ATP and GDP as substrates. 2′,3′-cGAMP is a high-affinity ligand for STING, an ER membrane protein that undergoes several structural conformations. 2′,3′-cGAMP bound to STING binds to the protein kinase TBK1, which phosphorylates IRF3; in addition, activated STING signals to IKK to phosphorylate and degrade IκBα, which sequesters NF-κB in the cytoplasm. Both phosphorylated and dimerized IRF3 and NFκB translocate to the nucleus to activate expression of type I interferons and other cytokines.

Endoplasmic Reticulum Stress Signaling Pathways

Most of the proteins that are secreted or delivered to the cell surface are folded and assembled in the ER. Cells monitor this protein-folding capacity in the ER lumen, and when this capacity is exceeded, it triggers an intracellular signaling pathway termed the unfolded protein response (UPR). Excess of unfolded proteins in the ER is delivered for proteasomal degradation after retrotranslocation through a process known as ERAD (ER-associated degradation). There are three UPR signal transducers initiated by transmembrane ER resident proteins: IRE1 (inositol-requiring enzyme 1), PERK (double-stranded RNA-activated protein kinase [PKR-like ER kinase]), and ATF6 (activating transcription factor 6). Each branch activates a transcription factor: for IRE1, XBP1 (X-box binding protein 1), for PERK ATF4 (activated transcription factor 4), and for ATF6, a cleaved form ATF6(N). These transcription factors will reestablish protein folding; however, in case it is not resolved, cells will undergo apoptosis. IRE1 is a transmembrane protein with two enzymatic activities, kinase and endoribonuclease (RNase). IRE1 RNAse activity is triggered by its own oligomerization and cleaves XBP1 mRNA, excising an intron that is translated and translocated to the nucleus. Interestingly, immunoglobulin-secreting plasma cells need a larger ER network to cope with high rates of immunoglobulin synthesis. IRE1 and XBP1 are necessary in these cells to maintain protein folding and support immunoglobulin production and secretion. The other branch of the UPR is PERK, an ER transmembrane kinase that senses ER stress. When activated, PERK oligomerizes and autophosphorylates itself and the translation initiation factor eIF2a, inhibiting large part of mRNA translation. Some exceptions are mRNAs involved in the stress response that contain short open reading frames, such as ATF4 that drives expression of genes such as CHOP and others involved in the ER stress response. The third branch of the UPR is ATF6, a transcription factor localized at the ER membrane. Upon excess of unfolded proteins, ATF6 traffics to the Golgi apparatus, where it is cleaved by two proteases and translocated to the nucleus and activate genes involved in the ER response including chaperones.

Heme Signaling Transduction

Heme (iron protoporphyrin IX) is a prosthetic group in numerous proteins, such as globins, functioning in oxygen transport or electron transfer. Heme is mainly synthesized in a series of reactions in the cytoplasm and mitochondria of the bone marrow and liver. Heme degradation starts in spleen macrophages involving heme oxygenase that produces biliverdin, that is converted to bilirubin by biliverdin reductase that is transported to the liver. Heme levels are tightly controlled in cells through sensing and signaling mechanisms that include kinases and transcription factors that regulate heme synthesis and/or degradation. In reticulocytes, heme signaling is controlled through HRI (heme-regulated inhibitor) kinase that phosphorylates eIF2a (eukaryotic initiation factor a), coordinating protein synthesis with heme availability. Incorporation of heme into globin chains avoids the aggregation and proteotoxicity of unassembled heme-free globin chains. HRI has several structural domains that include two kinases domains with two binding sites for heme, one reversible in a kinase domain that senses heme levels, and one stable heme binding domain in the N-terminus. Under low intracellular heme levels (e.g., dietary iron deficiency), reduced heme binding to the HRI reversible site activates its kinase activity and phosphorylates eIF2a, reducing global protein synthesis, including globin synthesis. HRI activation also increases peIF2a-dependent translation of ATF4, a transcription factor involved in integrated stress responses. HRI and ATF4 are necessary for erythroid differentiation. Other heme-sensing proteins include the transcriptional repressor Bach1 (BTB domain and CNC homolog 1) that is negatively regulated by heme and controls globin gene expression. Bach1 heterodimerizes with Maf DNA-binding proteins that bind to globin and oxidative stress promoters, such as heme oxygenase 1 gene promoters. Bach1 heme-binding domains are near the C-terminus that contains cysteine-proline motifs. High intracellular heme concentrations bind to Bach1 and promote translocation from the nucleus to the cytoplasm; thus Bach1 targets increases in these conditions, promoting hemoglobin synthesis.

Hypoxia Signaling Transduction

Human cells adapt to oxygen concentrations through signaling mechanisms that involve changes in gene expression, including the erythropoietin and glycolytic enzymes. Oxygen is sensed through a family of enzymes called EGLN or PHD prolyl hydroxylase enzymes that are 2-oxoglutarate-dependent dioxygenases whose activity depends on oxygen levels. A major substrate of these enzymes is the hypoxia-induced factor HIF1a that, once hydroxylated on two prolines, binds to VHL, causing ubiquitination and subsequent degradation. Physiologic hypoxia occurs in the hematopoietic stem cell niche and facilitates survival.

METABOLOMICS AND CONTROL OF HEMATOPOIETIC CELL METABOLISM

There are three important general pathways by which metabolism impacts cellular function and the metabolomic state contributing to cell, tissue, and human body physiology or pathology (Fig. 6.3): (1) activity of catabolic routes that supply energy in the form of ATP, such as glycolysis or oxidative phosphorylation; (2) activity of anabolic routes that synthesize molecules that are used for cellular growth or a specific cellular function; and (3) changes in metabolites that control intrinsic and extrinsic cellular activities. This regulation is intimately connected to signaling transduction, because most of the pathways described in the previous section directly control cellular metabolism and metabolite levels. Here, this part of the review will cover the main metabolic pathways and new metabolomic research, taking into consideration their implications in hematopoietic cells.

Glucose Metabolism

Hematopoietic cells have different types of glucose transporters; for example, activation of T cells causes dramatic increases in Glut1 expression to maintain immune homeostasis. Once transported into the cell, glucose is metabolized through different biochemical pathways to provide energy and building blocks for macromolecules that constitute the cell or regulatory metabolites. Glucose can be stored in cells in the form of glycogen, which constitutes a rapid source of energy through its breakdown to free glucose (glycogenolysis), although this pathway is limited to a certain number of hematopoietic cells. Chemotaxins (FMLP, C5ades arg, arachidonic acid) activate granulocytes to catabolize significant amounts of endogenous glycogen.

Glycolysis

Glycolysis is a series of chemical reactions by which six-carbon glucose is converted into two three-carbon keto-acids (pyruvate). Importantly, these oxidative reactions generate energetic molecules such as ATP and NADH and can occur in the absence of oxygen and mitochondria. In some cells, such as erythrocytes, anaerobic glycolysis produces lactate, but in most cell types pyruvate is completely oxidized to acetyl coenzyme-A (acetyl-CoA) and carbon dioxide by the mitochondrial pyruvate dehydrogenase complex and the tricarboxylic acid (TCA) cycle coupled to oxidative phosphorylation. In general, hematopoietic stem cells are thought to largely depend on glycolysis, whereas more differentiated cells, except for erythrocytes, use mitochondrial oxidative metabolism. Glycolytic fluxes are under intrinsically tight control through intermediate metabolites in the pathway. The most powerful control is exerted by fructose 2,6-bisphosphate (F-2,6-BP), which is generated by phosphofructokinase 2. F-2,6-BP allosterically activates phosphofructokinase, providing a "feed-forward" mechanism of stimulation. Activation of growth factor signaling pathways potently stimulates glycolysis at different points, including phosphorylation of phosphofructokinase 2 and pyruvate kinase cell-specific isoforms. The PI3K pathway is a major signaling pathway that controls glycolysis.

Figure 6.3 INTEGRATION OF CENTRAL METABOLIC PATHWAYS. The metabolic fluxes within anabolic and catabolic routes are controlled by different signals including metabolite concentrations. These metabolic pathways are localized in different cellular compartments to adequately provide cellular energetic and nutrient homeostasis necessary for growth and survival. See text for further details. *ACC*, Acetyl-CoA carboxylase; *CoA*, coenzyme A; *FAS*, fatty acid synthase; *LDHA*, lactate dehydrogenase A; *PDH*, pyruvate dehydrogenase; *PDK*, pyruvate dehydrogenase kinase; *ROS*, reactive oxygen species; *TCA*, tricarboxylic acid.

Interestingly, in erythrocytes, 1,3-diphosphoglycerate can be diverted from glycolysis to synthesize 2,3-diphosphoglycerate (2,3-DPG) via the enzyme diphosphoglycerate (Rapoport-Laubering shunt). 2,3-DPG is an important metabolite that regulates oxygen binding to hemoglobin; thus increased levels of 2,3-DPG (e.g., under hypoxic conditions) allow hemoglobin to release oxygen under low partial oxygen tensions.

Pentose Phosphate Pathway

The pentose phosphate pathway (PPP) derives from glycolysis in the cytoplasm. The first enzyme in this pathway is glucose-6-phosphate dehydrogenase (G6PDH) and produces NADPH, a substrate used for lipogenesis and glutathione regeneration by glutathione reductase. The regulation of NADPH production through G6PDH is through NADPH-mediated product inhibition. The PPP is also important in generating ribose-5 phosphate, which is a precursor for nucleotide synthesis in proliferating cells. Interestingly, G6PDH deficiency leads to low levels of NADPH, which is essential for controlling ROS through glutathione reductase. It is one of the most common erythrocyte enzymopathies, and these cells cannot prevent oxidative damage in critical molecules such as heme, causing overall irreparable damage to the cell at a much higher rate than normal, particularly in response to certain environmental triggers such as drugs and stress. The damaged erythrocytes are removed from circulation in the spleen and destroyed by macrophages at an elevated rate, leading to anemia. This enzymopathy occurs in areas with high malarial burden, in part because the mutated recessive allele confers malarial resistance. This resistance is because RBCs with low G6PDH activity, when infected with the parasite, are continuously removed from the circulation.

Tricarboxylic Acid or Krebs Cycle

A major route for pyruvate oxidation is conversion to acetyl-CoA, a reaction catalyzed by the mitochondrial pyruvate dehydrogenase enzymatic complex. Acetyl-CoA is a high-energy intermediate that can be further oxidized by the TCA cycle or used for fatty acid synthesis. The TCA cycle is initiated by the condensation of oxaloacetic acid with acetyl-CoA, forming citrate. In reactions involving decarboxylation and oxidation, CO_2 is produced and NADH and flavin adenine dinucleotide (FADH) are produced for use in the mitochondrial respiratory chain. The flux of the TCA cycle is regulated by the levels of acetyl-CoA and oxaloacetic acid, which are entry points in the cycle, and by the availability of NAD^+ and FAD^+ substrates. The rate of oxidation through the TCA cycle depends on mitochondrial electron transport activity, which is governed in part by NADH and ADP levels. The TCA cycle also produces metabolites for biosynthetic processes (anaplerotic reactions). For example, citrate is converted to fatty acids and sterols, oxaloacetate is used to produce aspartate to be used in biosynthesis of nucleotides, aconitate generates itaconate that attenuates inflammation in LPS-activated macrophages, and succinyl CoA is an intermediate in heme and porphyrin synthesis. Aside from the bioenergetic and anaplerotic aspect of this cycle, several reactions have important clinical implications.

Oxidative Phosphorylation

In most cell types, oxidative phosphorylation is dominant on ATP generation. Exceptions include RBCs, which lack mitochondria. Oxidative phosphorylation complexes are located at the inner mitochondrial membrane and receive high-energy electrons from NADH (produced from the oxidation of acetyl-CoA). These electrons are passed through the different oxidative phosphorylation complexes (which contain heme, copper iron–sulfur groups, and flavins as electron carriers) until they reach the final electron acceptor, molecular oxygen. Because of electron transfer, protons are pumped into the mitochondrial intermembrane space, generating an electrochemical gradient used to synthesize ATP. There are five oxidative phosphorylation complexes: complex I (NADH–CoQ reductase complex), complex II (succinate–CoQ reductase complex), complex III ($CoQH_2$–cytochrome c reductase complex), complex IV (cytochrome C oxidase complex), and complex V (ATP synthase complex). In general, hematopoietic stem cells are in low-oxygen niches and largely depend on glycolysis instead of oxidative phosphorylation to maintain ATP levels. The differentiation process is associated with increases in mitochondria, which allow for the generation of ATP through the respiratory chain. For example, this occurs in quiescent T cells that are in a catabolic phase, producing ATP mainly through oxidative phosphorylation. Upon stimulation, activated T cells shift towards an anabolic phase, relying upon a high rate of glycolysis for ATP generation. In addition, oxidative phosphorylation plays an important role in immune antitumor responses. Thus the tumor microenvironment is known to repress T-cell mitochondrial biogenesis to facilitate tumor growth. Similar oxidative phosphorylation repression is caused by the inhibitory receptor PD-1 driving CD8(+) T-cell exhaustion. Another example relates to cellular metabolism in M1 and M2 macrophages. M1 macrophages are largely glycolytic to function during acute inflammation. In contrast, M2 macrophages mainly use oxidative phosphorylation for lengthy processes to resolve tissue inflammation and repair or to promote antiparasite immunity. Mitochondrial DNA encodes for several oxidative phosphorylation subunits, and mutations in this DNA produce mitochondrial diseases. Interestingly, anemia, a symptom associated with patients having Pearson syndrome, is caused by accumulation of mutated mitochondrial DNA in sideroblasts. This suggests that hematopoietic cell–specific respiration defects can be responsible for anemia by inducing abnormalities in erythropoiesis during development.

Reactive Oxygen Species Metabolism

ROS are chemically reactive small molecules with oxygen in different oxidation states, such as partially reduced oxygen ions and peroxides. The three major species are superoxide, hydrogen peroxide, and hydroxyl radicals. The major cellular sites for ROS production are the mitochondria and NADPH oxidase, a plasma membrane or phagosome-bound enzyme. Approximately 85% of cellular ROS is a subproduct of normal oxidative phosphorylation. Superoxide is the initial ROS produced in the electron transport chain, and it is transformed to hydrogen peroxide by the enzyme superoxide dismutase. Hydrogen peroxide is the substrate of catalase or glutathione peroxidase, which reduces it to water. However, hydrogen peroxide is also converted to hydroxyl radicals, the most ROS, in a Fenton reaction with ferrous iron. NADPH oxidase catalyzes the NADPH-dependent reduction of oxygen into the superoxide anion.

ROS cause cellular damage through oxidation and chemical modifications of proteins, lipids, and DNA. Nuclear and mitochondrial DNA can be oxidized, producing strand breaks. Intracellular levels of ROS are regulated through different signaling transduction pathways. Growth factor–mediated signaling increases ROS levels, for instance. Conversely, ROS also affect this signaling through modulation of PTPs that contain cysteine-sensitive residues that modulate their enzymatic activity and regulate the biologic responses associated with this signaling.

ROS are particularly deleterious to hematopoietic stem cells because of their effect on genomic stability and survival. In phagocytic cells (neutrophils, macrophages, or eosinophils), NADPH oxidase is responsible for the oxidative burst that is triggered upon phagocytosis of pathogens. Superoxide generated by NADPH oxidase is rapidly converted to other ROS, which, in cooperation with pH-sensitive proteases, are responsible for killing the microorganisms in the phagosome vacuole.

Cell death via ferroptosis occurs with extensive phospholipid-containing polyunsaturated fatty acid chains peroxidation caused by transition metal iron-dependent ROS production. Certain blood tumors such as diffuse larger B-cell lymphomas are very susceptible to ferroptosis, which is often associated with mesenchymal and metastatic states. An important regulator in this process is GPX4 (glutathione peroxidase 4), a selenium-dependent enzyme that uses reduced glutathione to inhibit phospholipid peroxidation. Excessive iron-dependent phospholipid peroxidation disrupts membrane integrity causing cell death that can be inhibited by GPX4 inhibitors, antioxidants, or iron quelators.

Recently, gain-of-function mutations of isocitrate dehydrogenase 1 and 2 (IDH1 is cytoplasmic and is unrelated to the TCA cycle; IDH2 is the TCA mitochondrial form) have been found in 20% of acute leukemia patients. IDH1 and IDH2 are highly homologous but distinct (in structure and function) from the NAD$^+$-dependent heterotrimeric IDH3 enzyme that is part of the TCA cycle producing NADH to the respiratory chain. The cellular function of the NADP-dependent IDH1/2 enzymes is not clear, but they are part of glucose, fatty acids, and glutamine metabolism and contribute to the maintenance of cellular reduction-oxidation balance. In three identified mutations, the enzyme undergoes a change in its normal physiologic catalytic reaction (i.e., oxidative decarboxylation of isocitrate to produce α-ketoglutarate and CO_2 while converting NAD[P] to NAD[P]H) and instead produces 2-hydroxyglutarate, which is now considered to be a proto-oncometabolite. The mechanism appears to be linked to competition with α-ketoglutarate for the active site of ketoglutarate-dependent dioxygenases, such as TET2, which functions as a cytosine demethylase.

Lipid Metabolism

Fatty acids and triglycerides (the storage form of fatty acids) constitute an energetic reserve in the body. Most of the cells can synthesize fatty acids, but there are essential fatty acids such as linoleic acid, α-linoleic, and arachidonic acid that cannot be synthesized. Arachidonic acid is made from linoleic acid and is the precursor for prostaglandins, thromboxanes, and leukotrienes that participate in different pathways such as the inflammatory response. Drugs that block the enzyme cyclo-oxygenase and prostaglandin synthesis such as acetaminophen, ibuprofen, and acetylsalicylate provide pain relief. Fatty acids can directly mediate transcriptional responses, acting as ligands for peroxisome proliferator-activated receptors, a family of NHRs. In addition, there are specific GPCR receptors such as GPR40 and GPR120 activated by medium- or long-chain fatty acids. GPR43 is activated by short-chain fatty acids and is highly abundant in leukocytes.

Fatty Acid Synthesis

In the mitochondrial matrix, acetyl-CoA is generated from pyruvate and is the precursor for fatty acid synthesis. Acetyl-CoA cannot cross the mitochondrial membrane; thus acetyl-CoA condenses with oxaloacetate (first reaction in the TCA cycle) to form citrate that is exchanged into the cytoplasm through TCA translocases. Once in the cytoplasm, citrate is converted to acetyl-CoA by ATP citrate lyase. The rate-limiting reaction of fatty acid synthesis is the carboxylation of acetyl-CoA to form malonyl CoA, which is catalyzed by acetyl-CoA carboxylase (ACC). Malonyl CoA is a potent inhibitor of fatty acid oxidation. ACC is allosterically regulated by citrate to form active enzyme polymers, which are depolymerized by the end product of fatty acid synthesis: long-chain fatty acids. Growth factors positively control ACC dephosphorylation. In contrast, catecholamines result in the phosphorylation and inhibition of ACC via PKA. Fatty acids are synthesized in the cytoplasm by a multifunctional enzyme, FAS. Two of these functional domains are the acyl carrier protein and the condensing enzyme (CE). After completion of the different rounds of synthesis, the palmityl group is transferred to CoASH. In macrophages, LPS activates lipogenesis through activation of sterol regulatory element–binding protein (SREBP), a key transcriptional mediator of cholesterol and fatty acid synthesis.

Fatty Acid Oxidation

Fatty acids are "charged" before oxidation to form acyl-SCoA, a cytoplasmic reaction catalyzed by the enzyme fatty acyl-CoA synthetase. However, fatty acid β-oxidation occurs in the mitochondrial matrix, and charged fatty acids must first be conjugated to carnitine to cross the mitochondrial membrane. This transport is carried out by the carnitine acyltransferases I and II. These enzymes constitute a rate-limiting step for β-oxidation of fatty acids and are allosterically regulated by malonyl CoA, allowing the cell to avoid a futile cycle of fatty acid synthesis and breakdown. Inside the mitochondria, acyl-CoA undergoes a cycle of reactions removing acetyl-CoA from the main chain. This acetyl-CoA is then processed through the TCA cycle.

Cholesterol

Cholesterol is an important component of cellular membranes and a substrate to produce steroid hormones. Free cholesterol is tightly controlled in cells through synthesis, storage, and transport. Excess cholesterol in cells is secreted through reverse cholesterol transport or stored in the cytoplasm as cholesterol ester, produced by Acy-CoA:cholesterol acyltransferase located in the ER. Cholesterol is transported in the plasma by lipoproteins, including chylomicrons and very-low-density lipoprotein (VLDL). The main sources of cellular cholesterol for hematopoietic cells are the cholesterol-rich lipoprotein, low-density lipoprotein (LDL), and de novo synthesis from acetyl-CoA. The rate-limiting step for cholesterol synthesis is catalyzed by hydroxymethylglutaryl (HMG)-CoA reductase, the direct target of cholesterol-lowering statin drugs, and converts HMG-CoA to mevalonic acid. Cellular cholesterol levels are sensed in the ER through the SREBP transcription factor, which directly controls most the enzymes in cholesterol synthesis as well as LDL transport. Excess of LDL becomes oxidized and taken by macrophages, a main cause of atherosclerosis. The SREBP pathway is also important for T-cell activation under antigenic challenge, because its activation favors cholesterol synthesis and transport, which is used for membrane biogenesis and cell proliferation in the activated T cell.

Phospholipids

Phospholipids contain a hydrophilic head with a glycerol phosphate group that is esterified to a hydroxyl group of serine, choline, or ethanolamine, and two hydrophobic tails that are fatty acids esterified to two of the carbons of glycerol phosphate. They are main constituents of cellular membranes and form the lipid bilayer. Phospholipid synthesis takes place in the ER membrane, and they are delivered to cellular membranes. Some types of phospholipids also form part of signaling transduction as substrates for phospholipase C. Phospholipids are unequally distributed among organelle membranes and are also asymmetrically localized between the two sides of the bilayer. For example, phosphatidylcholine (PS) is enriched in the inner part of the plasma membrane and becomes exposed during cell death and targeted through the macrophage's PS receptor. The synthesis of phospholipids starts with DAG or cytidine diphosphate (CDP)-DAG that is formed from phosphatidic acid, which is made from the glycolytic intermediate glycerol-3-phosphate or dihydroxyacetone phosphate. Specific enzymes synthesize PS, phosphatidylethanolamine, and phosphatidylserine. PS is made via the Kennedy pathway via CDP-choline. A potent phospholipid that plays important roles in leukocyte chemotaxis, macrophage oxidative burst, and platelet aggregation is the platelet-activating factor (acetyl-glyceryl-ether-phosphorylcholine).

Amino Acid Metabolism

The major sources of amino acids derive from the diet or protein breakdown. Nonessential amino acids are synthesized from carbon skeletons using different metabolic pathways. Amino acids conjugated to transfer RNA (tRNA) are used in protein synthesis; however, in excess, they can be used for energy production. In addition, amino acids are necessary for the synthesis of other compounds. For example, tryptophan catabolism constitutes a route for de novo NAD^+ synthesis in a pathway that is important in leukocytes for the replenishment of NAD^+ levels after oxidative stress. Interestingly, different metabolites derived from tryptophan catabolism via the kynurenine pathway play a role in immune tolerance. Plasma amino acids are transported in cells against a concentration gradient. Amino acid transporters are specific for neutral (small and larger), basic, and acidic amino acids. Depending on the cell type and specific state (growth, hypoxia, fasting, and so on), intracellular amino acids are used in anabolic or catabolic pathways.

Most of the regulation of amino acid metabolism is achieved through substrate fluxes affecting specific enzyme kinetics. However, there are two major regulatory pathways that involve amino acid–sensing mechanisms and metabolic control. (1) General control nonrepressed 2 (GCN2) is a protein kinase that senses amino acid deficiency through direct binding to uncharged tRNA. GCN2 controls the transcription factor ATF4, affecting different enzymes of amino acid metabolism. The high asparagine requirement of certain acute lymphoblastic leukemias has resulted in the use of asparaginase to deplete circulating levels of asparagine. Limited amounts of asparagine result in activation of GCN2 in leukemic cells and reduce their proliferation and viability rates. (2) mTOR is a protein kinase activated in response to increased amino acid concentrations (particularly branch chain amino acids). mTOR controls many aspects involved in protein synthesis, inhibition of protein degradation, and amino acid biosynthetic enzymes.

Biosynthesis of Nonessential Amino Acids

Nonessential amino acids are synthesized by most of the cells, including hematopoietic lineages. Nonessential amino acids are mainly synthesized from glucose (alanine, arginine [from the urea cycle in hepatic cells], asparagine, aspartate, cysteine, glutamate, glutamine, glycine, proline, and serine), except for tyrosine, which is synthesized from phenylalanine. The rest of the nine amino acids are essential, and the body needs to obtain these from the diet. Serine, glycine, and cysteine are synthesized from glycolytic intermediates. Serine synthesis has recently been found to be increased and necessary in stem cells. For some hematopoietic cells, the synthesis of cysteine and glycine is of elevated importance owing to their use in the synthesis of the tripeptide glutathione. Aspartate and asparagines are synthesized by transamination of oxaloacetate by glutamate and amide transfer from glutamine, respectively. Glutamate, glutamine, proline, and arginine are formed from the TCA cycle intermediate α-ketoglutarate.

Amino Acid Catabolism

Two central reactions in amino acid catabolism are the generation of ammonia through transamination (catalyzed by amino transferases) and oxidative deamination (catalyzed by glutamate dehydrogenase) in which the α-amino group of the different amino acids is transferred to α-ketoglutarate to form glutamate, which undergoes the release of free NH_3. Free ammonium is added to glutamate to generate glutamine, which is then exported into the circulation to the liver, where it then enters the urea cycle. The urea cycle mainly occurs in the liver and has two purposes: (1) to get rid of free ammonium and (2) to supply arginine. Interestingly, one of the enzymes of the urea cycle, arginase (which converts arginine to ornithine), is expressed in immune cells. Myeloid cell arginase depletes arginine and suppresses T-cell immune responses and is an important mechanism of inflammation associated with immunosuppression. Arginase is viewed as a promising strategy in the treatment of cancer and autoimmunity. Arginine is also essential for the differentiation and proliferation of erythrocytes.

Nucleotide Metabolism

Nucleotides are involved in a diverse array of cellular functions, including (1) energy metabolism (ATP, NAD^+, $NADP^+$, and FAD^+ and their corresponding reduced forms), (2) units of nucleic acids (NTPs are substrates for RNA and DNA polymerases), and (3) physiologic mediators such as adenosine, ADP (which is critical in platelet aggregation), cAMP and cGMP (second messenger molecules), and GTP (which participates in signal transduction via GTP-binding proteins).

Most of the regulatory pathways that are associated with nucleotide synthesis and degradation are strictly controlled by regulatory components of the cell cycle machinery. The amount of intracellular nucleotides has to reach certain levels for the cell to proceed through the S-phase checkpoint. In addition, several of the key cell cycle regulators, including the c-myc oncogene (which is translocated in certain myelomas), directly increase the expression of most of the key enzymes associated with nucleotide synthesis.

Nucleotide Synthesis

There are two pathways for the synthesis of nucleotides, salvage and de novo. The salvage pathway uses free bases via a reaction with phosphoribosyl pyrophosphate (PRPP) and generation of nucleotides. De novo pathways synthesize pyrimidines and purine nucleotides from amino acids, carbon dioxide, folate derivatives, and PRPP. Importantly, both salvage and de novo pathways depend on PRPP, which is produced from ATP and ribose-5-phosphate (generated in the PPP) by PRPP synthetase, an enzyme that is inhibited by metabolic markers of low-energy AMP, ADP, and GDP to avoid nucleotide synthesis in these conditions. In general, PRPP levels are low in postmitotic cells but high in proliferating cells. Folate is essential in nucleotide biosynthesis, and lack of folate in the diet can lead to anemia due to inhibition of proliferation of RBC precursors.

Nucleotide Degradation

Nucleotidases and nucleosidases initially participate in purine nucleotide degradation. For example, adenosine is deaminated to produce inosine, which, after ribose is removed, generates hypoxantine, which is used by xanthine oxidase to form uric acid. Immune cells have potent nucleotide salvage pathways, and a lack of adenosine deaminase causes severe combined immune deficiency (SCID) syndrome. SCID is associated with a large accumulation of dATP in immune cells, which, through a negative-feedback mechanism on ribonucleotide reductase, blocks production of dNTPs and results in a failure to replicate DNA.

Introduction to Metabolomics

Analytical measurements of blood metabolites such as glucose, urea, and cholesterol are part of clinical biochemistry to track diseases. Along these lines and facing the new era of personalized medicine emerges metabolomics, which evaluates metabolism with a comprehensive and quantitative analysis of all metabolites, as well as its impact on cell biology, and aims to discover novel biomarkers or targets for therapy. Recent technical innovations in mass spectrometry and nuclear magnetic resonance (NMR) have allowed the measurement of many metabolites simultaneously. These advances, in combination with metabolite flux analysis with isotopic tracers, have provided new information on many metabolic processes. The use of metabolomics also offers a tool to identify metabolic enzymes as drug targets, because they are poised for inhibition with small-molecule drugs and possess allosteric sites that can be used to alter catalytic activity.

A major effort in metabolomics has been the identification of biomarkers for diseases and therapeutic targets. As an example, metabolomics was used to analyze plasma from diabetic patients showing increases in branch chain amino acids before hyperglycemia. Another example comes from the combination of genome-wide sequencing analysis and metabolomics: sequence analysis of AMLs was able to identify IDH1 or IDH2 mutations in 20% of patients. Metabolomics analysis revealed accumulation of a noncanonical metabolite, 2-hydroxyglutarate, which promotes the tumorigenic process (see following discussion). In addition, recent blood metabolomics profiles in critically ill COVID-19 patients identified increased kynurenine and decreased arginine, sarcosine, and lysophosphatidylcholines. In fact, the arginine/kynurenine ratio provided a classification accuracy between patients and healthy controls. In general, there are two different metabolomic approaches: targeted, which measures known and specific metabolites; and nontargeted, which includes analytical measurements of unknown metabolites.

Metabolomics of Glucose Metabolism

Systematic and simultaneous quantitative targeted polar metabolite analysis of glucose metabolic pathways using metabolomic and flux measurement techniques has introduced new basic and clinically relevant information in hematology (Fig. 6.4). For example, increases in glucose metabolism signatures measuring serum metabolite linked to glycolysis and the TCA cycle have been correlated with a prognostic risk score in AML patients.

Metabolic reprogramming or switches are crucial for T-cell activation. Quiescent naive T cells obtain most of their ATP from mitochondrial oxidative phosphorylation for energy, whereas activated T cells switch to glycolytic, glutaminolysis, and anabolic metabolism to promote clonal expansion that appears to be dependent on the transcription factor Myc. Moreover, metabolomic signatures have revealed that T helper (Th)1, Th2, and Th17 cell lineages and T effectors exhibit an increased glycolytic metabolism. However, regulatory T cells and CD8^{+} memory T cells depend more on mitochondrial oxidative phosphorylation. In addition, T cells are exposed to different nutrient environments, from high nutrient levels in the lymphoid organs to a more restricted nutrient availability in the effector sites such as tumors or infection. Under these conditions, metabolic reprogramming through mTOR and AMP kinases controls and maintains survival and immune function of T cells. Based on untargeted metabolomic studies, RBCs from G6PDH donors do not meet the US Food and Drug Administration (FDA) guidelines for storage quality because of pyruvate/lactate ratios and glycolytic and PPP intermediates involved in NADPH production.

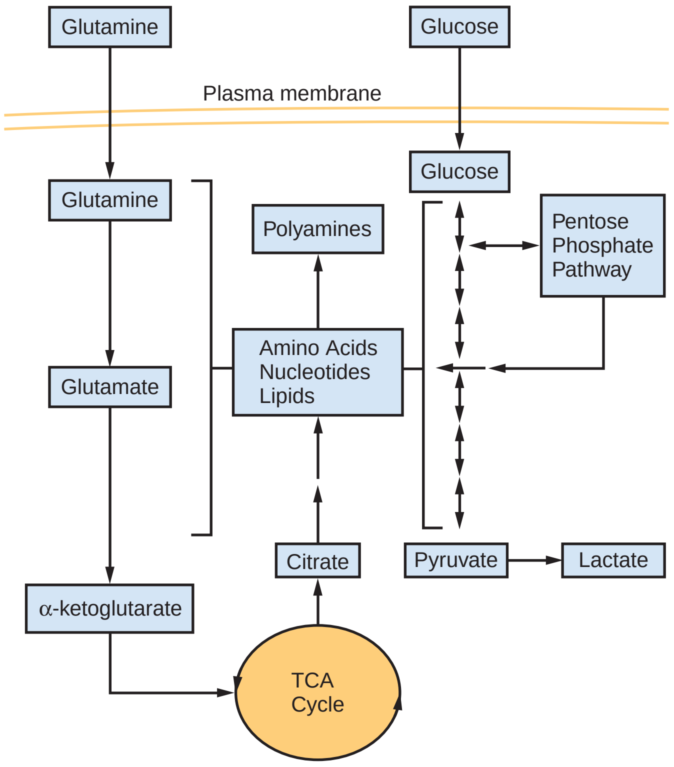

Figure 6.4 METABOLITE PROFILING UPON T-CELL ACTIVATION. Metabolomic analysis has revealed that glycolytic fluxes and glutaminolysis are increased during activation of T cells. Polyamines that are required for T-cell proliferation are synthesized from glutamine. See text for further details. *TCA*, Tricarboxylic acid.

Metabolomics of Lipid Metabolism

Nonpolar metabolomics has provided metabolite profiles linked to lipid metabolism. In the case of fatty acids, de novo fatty acid synthesis is necessary for differentiation of Th17. Bioactive lipids have also been profiled in different types of blood cells. For example, sphingosine-1-phosphate is stored in erythrocytes and is found highly elevated in the blood of sickle cell disease patients, owing to increased erythrocyte sphingosine kinase 1. Quantitative lipidomics platforms show that 20% of the platelet lipidomes is remodeled upon activation, including mainly arachidonic acid–containing lipids.

Metabolomics of Nucleotide Metabolism

Measurements of the different polar metabolites in nucleotide metabolism are linked to stages of cell growth. For example, unbiased metabolomics has identified that pyrimidine starvation is a mechanism for specific types of cell death in multiple myeloma cells. Hypoxanthine is one of the metabolite markers that is increased in plasma in different subtypes of lymphomas.

Metabolomics of Amino Acid Metabolism

Metabolomic studies have revealed that activated T cells reprogram their metabolism from fatty acid and pyruvate oxidation, and the TCA cycle, to aerobic glycolysis, the PPP, and glutaminolysis, and metabolic fingerprint-like tumor cells. Glutamine is used to increase polyamine biosynthesis, which is essential for T-cell proliferation, a process controlled by the transcription factor Myc. Metabolomic analysis of two cohorts of hematopoietic stem cell transplantation recipients and donors shows a significant change of host and microbiota indole metabolites related to tryptophan metabolism.

SUMMARY AND PERSPECTIVES

This short review summarizes the central signaling and metabolic pathways that play a pivotal role in all the processes executed by hematopoietic cellular systems. In normal physiologic conditions these pathways are regulated and operating to achieve homeostatic cellular functions in healthy individuals. However, in pathologic conditions, dysregulation or failure of these pathways leads to diseases of lymphohematopoietic tissues. To a large extent, the main components and regulatory circuitries of these pathways have been elucidated, but the challenge for the future is to fully integrate them and identify novel therapeutic targets that will enable the development of effective treatments for these diseases. New technologies in metabolomics are promising for the identification of biomarkers that can be used in personalized medicine, as well as new therapeutic targets including metabolic enzymes.

CHAPTER 7

PROTEIN ARCHITECTURE: RELATIONSHIP OF FORM AND FUNCTION

Jia-huai Wang and Michael J. Eck

Previous chapters outline the central dogma of mlecular biology: the storage of genetic information in DNA and its regulated transcription into messenger RNA and eventual translation into proteins. In this chapter, we briefly outline the chemical structure of proteins and their posttranslational modifications (PTMs). We explain how the properties of the 20 amino acids of which proteins are composed allow these polymers to fold into compact, functional domains and how particular domains and motifs have been assembled, modified, and reused in the course of evolution. Finally, we describe a sampling of proteins and domains of relevance to the hematologist and explore briefly how point mutations, chromosomal translocations, and other genetic alterations may modify protein structure and function to cause disease.

AMINO ACIDS AND THE PEPTIDE BOND

Proteins are linear polymers of the 20 naturally occurring amino acids, linked together by the peptide bond. All of the amino acids share a common core or backbone structure and differ only in the "sidechain" emanating from the central "α-carbon" (Cα) of this core. The common backbone elements include an amino group, the central Cα, and a carboxylic acid group. Peptide bonds are formed by reaction of the carboxylic acid of one amino acid with the amino group of the next amino acid in the chain. This reaction is templated and catalyzed by the ribosome. Coupling of multiple amino acids together via the peptide bond produces the repeating mainchain structure of the polypeptide chain, composed of the amide (NH) nitrogen, Cα, and carbonyl carbon (CO), followed by the amide nitrogen of the next amino acid in the chain (Fig. 7.1A). The resonant, partial double bond character of the peptide bond prevents rotation about this bond; thus the five mainchain carbon, nitrogen, and oxygen atoms of each peptide unit lie in a plane. The conformational flexibility in the polypeptide chain is conferred by rotation about the bonds on either side of the Cα atom; these bond angles are referred to as phi and psi angles. The angle of the N–Cα bond is the phi angle (Φ), and that of the Cα–CO bond is the psi angle (ψ).

The *primary structure* or primary sequence of a protein refers to the order in which various residues of the 20 amino acids are assembled into the polypeptide chain, and this sequence is critically important for determining the three-dimensional fold and thus function of the protein. The diverse chemical structure and physicochemical properties of the 20 amino acid sidechains guide the three-dimensional fold of proteins and also provide for the enormous repertoire of protein function, from catalysis of myriad chemical reactions to immune recognition to establishment of muscle and skeletal structure.

The amino acids can be divided into general classes based on the physicochemical properties of their side chains and in particular their propensity to interact with water. *Hydrophobic* amino acids have aliphatic or aromatic side chains and include alanine, valine, leucine, isoleucine, proline, methionine, and phenylalanine. The hydrophobic amino acids predominate in the interior of proteins, where they are sequestered from water. They tend to pack against each other via *van der Waals* interactions, which contribute to the overall stability of folded protein domains. By contrast, *hydrophilic* or *polar* amino acids (including serine, threonine, tyrosine, asparagine, glutamine, cysteine, and tryptophan) are often exposed on the surface of proteins, where they can form *hydrogen bonds* with each other, with the protein mainchain, and with water or ligand molecules. Hydrogen bonding refers to the attractive interaction of a proton covalently bonded to one electronegative atom (usually a nitrogen or oxygen in proteins) with another electronegative atom. Hydrogen bonds are an important contributor to the stability of proteins and to the specificity of protein-protein and protein-ligand interactions. *Charged* amino acids are also polar and are important participants in hydrogen bonding. Hydrogen bonds between negatively charged (acidic) and positively charged (basic) amino acids are also termed *salt bridges* and are also important components of protein stability and protein-protein interactions. The acidic amino acids are aspartate and glutamate, and the basic amino acids are lysine, arginine, and histidine. Histidine merits special mention because it is the only amino acid whose side chain can be protonated or unprotonated, and therefore charged or uncharged, around physiologic ranges of pH. For this reason, histidine is part of many enzyme active sites. For example, in the serine proteases of the coagulation cascade, an active site histidine acts as a general base, accepting and then releasing a proton in sequential steps of the enzymatic reaction. It is also important to note that some of the polar amino acids are *amphipathic* (i.e., they have both polar and hydrophobic character). This dual nature of threonine, lysine, tyrosine, arginine, and tryptophan makes them well suited for participating in protein-protein interactions, where they may be alternately exposed to solvent or buried upon formation of a complex.

The amino acid cysteine is unique in that its side chain contains a relatively reactive thiol group. The structure of cell-surface and extracellular proteins is often stabilized by *disulfide bonds*, covalent bonds formed between the thiol groups of spatially juxtaposed cysteine residues. In general, disulfide bonds are not found in intracellular proteins, where the reducing environment disfavors their formation. Disulfide bonds can form between cysteines within the same polypeptide chain, stabilizing the fold of the polypeptide backbone, or they may covalently join two different polypeptide chains, for example, the heavy and light chains of an immunoglobulin (Ig). In addition to their role in disulfide bond formation, cysteine residues often contribute to protein stability via their participation in metal ion coordination, in particular zinc, which is often bound by conserved sets of cysteine and histidine residues in small protein domains.

Protein Secondary Structure

The alternating pattern of hydrogen bond–donating amide groups and hydrogen bond–accepting carbonyl groups gives rise to repeating elements of protein structure that are stabilized by hydrogen bonds between these mainchain groups. These *secondary structure* elements include α-helices and β-sheets. In an α-helix, the mainchain adopts a right-handed helical conformation in which the carbonyl oxygen of the i^{th} residue in the polypeptide chain accepts a hydrogen bond from the amide nitrogen of the $(i + 4)^{th}$ residue (see Fig. 7.1B). The pattern may repeat for only a few residues, forming a single turn of α-helix, or for more than 100 residues, forming dozens of turns of helix. There are 3.6 residues per turn of helix, and the pitch or rise of the helix is

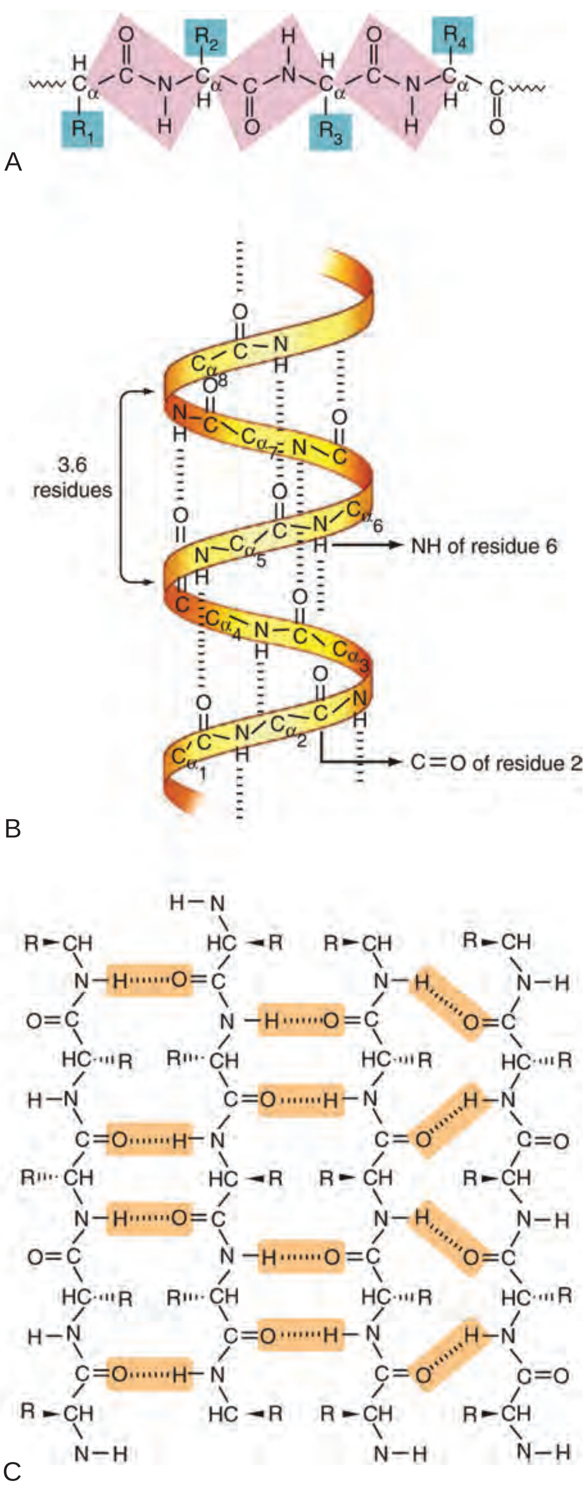

Figure 7.1 (A) Diagram showing a polypeptide chain where the mainchain atoms are represented as peptide units, linked through the α-carbon (Cα) atoms. Each peptide unit is a planar, rigid group *(shaded pink)* and has two degrees of freedom; it can rotate around the Cα-CO bond and the N-Cα bond. The peptide bonds are depicted in the trans conformation; adjacent Cα carbons and their side chains *(highlighted blue)* on opposite sides of the N–Cα bond. This is the preferred configuration for most amino acids because it minimizes steric hindrance. (B) The α helix. The hydrogen bonds between residue *n* and residue *n* + 4, which stabilizes the helix, are shown as dashed lines. (C) Schematic drawing of a mixed β-sheet. The three β-strands on the left are antiparallel to one another, while the two rightmost β-strands are parallel. The hydrogen bonds that stabilize the sheet are shaded.

1.5 Å per residue or 5.4 Å per turn. The sidechains of residues in an α-helix project outward, away from the central axis of the helix. Often a polar sidechain will "cap" the end of a helix by forming a hydrogen bond with the otherwise unpartnered amide or carbonyl group at the N- or C-terminal end of the helix.

In β-sheet secondary structure, the protein backbone adopts an extended conformation and two or more strands are arranged side by side, with hydrogen bonds between the strands. The strands can run in the same direction (parallel β sheet) or antiparallel to one another, and both parallel and antiparallel strands are often found together in mixed sheets (Fig. 7.2C). In β-sheets, the sidechains of a given strand extend alternately above and below the plane defined by the hydrogen-bonded mainchains. Other common types of secondary structure include a variant of the helix with an $i + 3$ hydrogen bonding pattern (the 3_{10} helix) and specific types of β-turns, short segments connecting other elements of secondary structure that are stabilized by β-sheet–like hydrogen bonds. Although any of the amino acids can be found within α-helices or β-sheets, the special characteristics of proline and glycine merit mention. The cyclic structure of proline means that it lacks an amide proton; thus it introduces an irregularity in hydrogen bonding. For this reason, it is infrequently found in α-helices, but if present, it will introduce a "kink" stemming from its constrained structure. Glycine lacks a sidechain—it has only a second hydrogen atom on its Cα—and therefore has less steric restriction and can adopt a wider range of backbone phi and psi angles. This added flexibility means that it tends to disfavor regular secondary structure.

Because proteins are large and complicated structures, they are typically illustrated with "ribbon" diagrams that trace the path of the polypeptide backbone. In such representations, helices are drawn as helical coils or cylinders, and β-strands as elongated rectangles with an arrow as a guide to the direction of the protein chain from its amino- to carboxy-terminal end.

Posttranslational Modifications

The covalent structure of proteins is commonly modified in structurally and functionally important ways beyond the linear coupling of amino acids via the peptide bond. Regulated proteolysis can be considered a PTM and can serve an important regulatory role, as in the cleavage of prothrombin in the blood clotting cascade.

A number of functional groups are appended to proteins to regulate their function, localization, protein interactions, and degradation. Examples of these PTMs include phosphorylation, glycosylation, ubiquitination, methylation, acetylation, and lipidation.[1] PTMs occur at distinct amino acid side chains or peptide linkages and are most often mediated by enzymatic activity and can occur at any step in the "life cycle" of a protein. As discussed later, a number of protein domains have evolved to recognize and bind specifically to proteins labeled by a particular PTM. Protein *phosphorylation*, most commonly on serine, threonine, or tyrosine residues, is one of the most important and well-studied PTMs. Phosphorylation is mediated by protein kinases and can activate or deactivate many enzymes through conformational changes and as such plays a critical role in the regulation of many cellular processes, including cell cycle, growth, apoptosis, and signal transduction pathways. Protein *glycosylation* encompasses a diverse selection of sugar-moiety additions to proteins that ranges from simple monosaccharide modifications to highly complex branched polysaccharides. Glycosylation has significant effects on protein folding, conformation, distribution, stability, and activity. Carbohydrates in the form of asparagine-linked (N-linked) or serine/threonine-linked (O-linked) oligosaccharides are major structural components of many cell surface and secreted proteins and also many viral proteins. Protein *methylation* on arginine or lysine residues is carried out by methyltransferases with S-adenosyl methionine (SAM) as the primary methyl group donor. Methylation is an important mechanism of epigenetic regulation because histone methylation and demethylation influence the availability of DNA for transcription. N-*acetylation*, the transfer of an

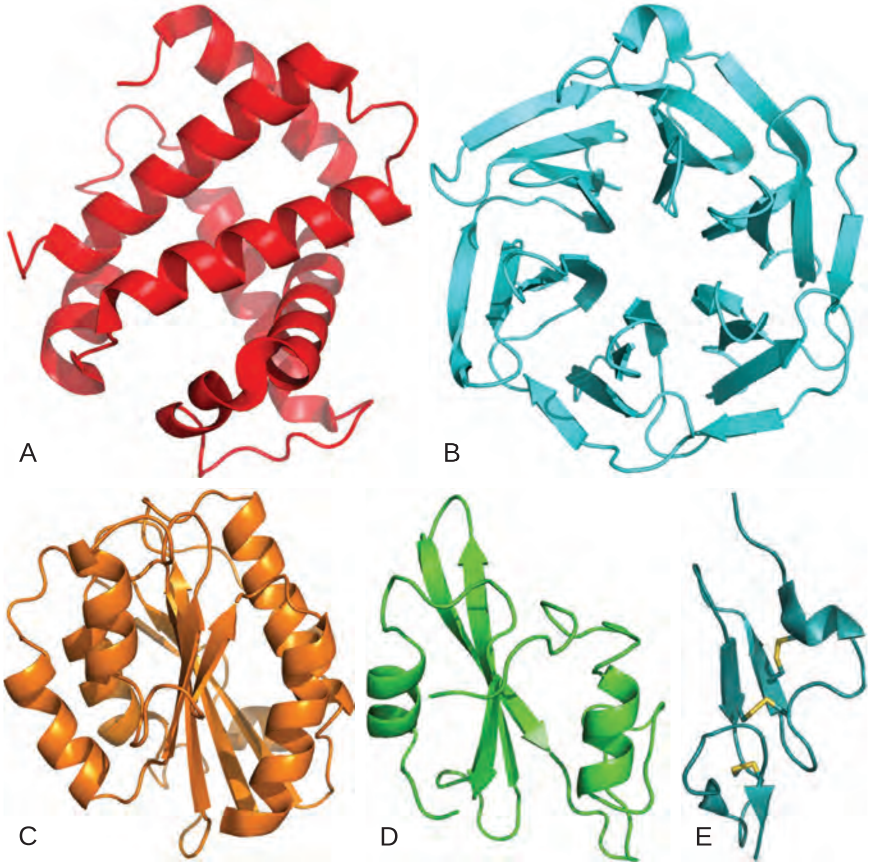

Figure 7.2 SEVERAL COMMON DOMAIN STRUCTURES. (A) The α-globin domain of hemoglobin is all α-helical (PDB entry 2MHB). (B) The β-propeller domain is an all β-strand structure found in many extracellular matrix and cell surface proteins (PDB entry 1NPE). (C) The integrin "I" domain is composed of alternate β-strands and α-helices (PDB entry 1ID0). (D) The SH2 (Src homology-2) domain is found in proteins involved in tyrosine kinase signaling and is also a mixed α/β-fold (PDB entry 1FMK). Its structure is stabilized by 3 to 4 disulfide bonds (PDB entry 1UZJ). *PDB*, Protein Data Bank.

acetyl group to the amine nitrogen at the N-terminus of the polypeptide chain, occurs in a majority of eukaryotic proteins. Lysine acetylation and deacetylation is an important regulatory mechanism in a number of proteins. It is best characterized in histones, where histone acetyl transferases (HATs) and histone deacetylases (HDACs) regulate gene expression via modification of histone tails. Many cytoplasmic proteins are also acetylated, and therefore acetylation seems to play a greater role in cell biology than simply transcriptional regulation.[2] *Lipidation* is a modification that targets proteins to membranes in organelles, vesicles, and the plasma membrane. Examples of lipidation include *myristoylation, palmitoylation, and prenylation*. Each type of modification gives proteins distinct membrane affinities, although all types of lipidation increase the hydrophobicity of a protein and thus its affinity for membranes. In N-myrisoylation, the myristoyl group (14-carbon saturated fatty acid) is transferred to an N-terminal glycine by N-myristoyltransferase. The myristoyl group does not always permanently anchor the protein in the membrane; in a number of proteins the N-terminal myristoyl group has been observed to pack into the protein core. N-myristoylation can therefore act as a conformational localization switch in which protein conformational changes influence the availability of the handle for membrane attachment.

Finally, ubiquitination (or equivalently, *ubiquitylation*) involves modification of a target protein with the protein ubiquitin, which is typically attached to a lysine residue via an isopeptide bond with the C-terminus of ubiquitin. Modification with ubiquitin, either singly (monoubiquitination) or in chains (polyubiquitination), is used to regulate diverse processes from protein degradation to gene expression to the cell cycle.[3]

The Domain Structure of Proteins

In general, the minimal biologically functional unit of protein three-dimensional structure is the protein *domain*. Domains are locally compact and semi-independent units of usually contiguous polypeptide chain. The common size of a domain is between 100 and 200 amino acid residues, although much larger and smaller domains are also frequently observed. Protein domains are composed of closely packed secondary structure elements—α-helices, β-sheets, or a combination of both—and the loops that connect them. Domains are stabilized by hydrophobic interactions among these elements and typically have very hydrophobic central cores, with more hydrophilic amino acids extending from their surface. Alternating patterns of hydrophobic residues in secondary structure elements are a reflection of the role of hydrophobicity in driving protein folding and stability. Helices are often amphipathic and pack in a folded domain such that their hydrophobic face is buried in the domain interior and their hydrophilic face is exposed on the surface. Likewise, β-sheets often have a buried hydrophobic face and an exposed hydrophilic face. The importance of the hydrophobic core to the stability of protein domains is highlighted by the fact that point mutations that introduce polar or charged residues into the protein interior often cause misfolding and thus a loss of function. Although these general characteristics are shared by protein domains that are found in an aqueous environment, such as those in the cytosol or on the cell surface, membrane-embedded proteins have very different properties reflective of their residence in the lipid bilayer. Several common domain structures representing different categories with regard to their secondary structure composition are shown in Fig. 7.2.

Deciphering this basic protein building block is key for understanding the structure and evolution of proteins. Kinetically, the domain structure of a protein may simplify the folding process into a step-wise course.[4] Thus a long amino acid sequence may fold into multiple domains rapidly and correctly. For many proteins, individual domains fold in a cotranslational manner; from the N-terminal region, a growing nascent polypeptide chain immediately begins to fold domain-by-domain during translation from the ribosome in a very efficient manner.[5] Genetically, it was long suspected that the exon structure of genes was correlated with the domains structure of proteins.[6] Recent multigenome analysis does find a strong correlation between domain organization and exon-intron arrangement in genomic DNA. The exon-domain correlation facilitates extensive exon shuffling events during evolution,[7] although it is not necessarily always one-exon/one-domain. This mechanism ensures that a stable and functionally efficient domain can be repeatedly used as a module assembled into many proteins with shared functions.

Not all protein sequences fold into a compact domain. Depending on computational methods used, 35% to 50% of the human proteome is estimated to lack a folded three-dimensional structure. Nevertheless, these *intrinsically disordered* proteins (or more often, intrinsically disordered regions within proteins) can perform critically important biologic functions that complement those of structured proteins.[8] Many disordered regions mediate protein-protein interactions and may undergo a disorder-to-order transition upon binding to an interacting partner, a process dubbed as folding-upon-binding. They function in crucial areas such as transcriptional regulation, translation, and cellular signal transduction.[9] Unstructured segments are well suited for protein interactions controlled by PTMs. For example, sites of tyrosine phosphorylation are typically unstructured and therefore accessible for modification, but after phosphorylation they become ordered upon phosphorylation-dependent binding to a partner protein.

Genomic analysis indicates that a large majority of known protein sequences arise from new combinations of various domains, and consequently more than 70% of all sequences can be at least partially modeled from known structures with homologous domains,[10] thanks to a large and growing database of experimentally determined macromolecular structures available in the *Protein Data Bank*.[11] This database of known structures has also fueled advances in our ability to computationally predict unknown protein folds.[12]

Although most new proteins arise from gene duplications or reshuffling of existing protein-encoding elements, this is not always the case; at least one-tenth may have arisen de novo from noncoding region of the genome.[13] Only a few percent of the human genome actually encodes functional genes. Vast regions of DNA that do not encode genes or regulate their expression may constitute a reservoir for creation of new protein-encoding genes.

Most proteins are composed of multiple domains, which may confer multiple functions, couple a targeting function to a catalytic function, or provide for allosteric regulation. In the following sections we highlight the structure of a few proteins and domains that are of central and recurring importance in hematology, to illustrate the relationship between domain architecture and function. We discuss representative examples from the extracellular space (the Ig domain), intracellular signaling (protein kinase domain), and the cell membrane (G protein–coupled receptors [GPCRs] and the vitamin K receptor).

The Immunoglobulin Domain and Variations

As implied by its name, the Ig domain was first recognized in antibodies.[14] A detailed discussion on antibody biology can be found in the Chapters 22 and 23. The human genome project has identified the Ig superfamily (IgSF) as the largest superfamily in the human genome, due to its extensive usage in the immune system.[15] Although Ig-like domains also exist in a few intracellular proteins, they are found predominately in the extracellular space and are the most abundant structural unit found in cell surface receptors, serving key recognition functions in both the immune and nervous systems. Along with a handful of other modular domains such as fibronectin type III domains and epidermal growth factor (EGF) domains, they form modular structures of most receptor molecules on the cell surface.

An Ig domain is composed of approximately 100 residues, folding into two β-sheets packing face-to-face, forming a β-barrel. This distinctively folded structure is commonly known as the Ig fold (Fig. 7.3A). An intact IgG antibody consists of two heavy chains and two light chains. Each heavy chain contains four Ig domains, one "variable" domain and three "constant" domains, and each light chain contains two Ig domains, one variable and one constant. The variable and constant Ig domains differ somewhat in structure and

are correspondingly classified as V-set and C-set Ig folds. A V-set Ig domain has β-strands A, B, E, and D on one sheet and A′, G, F, C, C′ and C″ strands on the other (see Fig. 7.3A), whereas a C-set Ig domain lacks A′, C′ and C″ strands on either edge (Fig. 7.3B). In both, the two sheets are linked together by a conserved disulfide bond between the B and F strands (reviewed in Williams et al.[16]). Within variable domains, hypervariable sequences are found in three connecting loops at one end of the domain. These loops are termed complementarity determining regions (CDRs) (see Fig. 7.3A). In the intact antibody, the CDRs of the heavy and light chains combine to make up the antigen-binding site. Fig. 7.4A depicts how the CDRs of a human immunodeficiency virus (HIV)-neutralizing antibody form an antigen-binding pocket that recognizes an antigenic peptide from an HIV surface protein.[17]

A similar structural platform is used in cellular immunity by T-cell receptors (TCRs), which, distinct from antibodies, recognize an antigenic peptide along with the major histocompatibility complex (MHC) molecule that presents the peptide on surface of an infected or cancerous cell. The complete TCR is a membrane-spanning complex with CD3 that contains a total of eight Ig domains—two in each of the TCR α- and β-chains, and one in each of the dimeric CD3γε and CD3δε subunits. The CD3ζζ subunit, which contains only transmembrane helices and cytoplasmic tails, completes the receptor. Recent advances in cryoelectron microscopy (cryo-EM) have allowed elucidation of the structure of the intact TCR-CD3 complex,[18] revealing an overall architecture in which the extracellular "bouquet" of Ig domains is arranged on "stems" of eight transmembrane helices (Fig. 7.4B). Within this complex the CDR3 loops of the TCR α and β variable domains play a key role in antigen recognition, whereas germline-encoded CDR1 and CDR2 loops of the TCR are responsible for contacting the polymorphic region of the MHC molecule, with CDR1 also taking part in peptide binding.[19,20] Fig. 7.4C illustrates a typical crystal structure of a TCR in complex with an antigenic peptide bound to the MHC molecule. An extensive discussion on the role of these proteins in cellular immunity can be found in Chapter 24.

A number of variations on the Ig fold are found in other cell surface receptors. These Ig-like domains include the topologically similar fibronectin type III domains and the domains of cadherins, both of which lack the disulfide bridge found in the canonical Ig domain. Further variations are found in modular cell surface receptors, which often have a V-set Ig-like domain at their N-terminus, positioned to extend from the plasma membrane for ligand-binding, serving a role analogous to antigen-recognition. By contrast, "I-set" Ig-like domains (see Fig. 7.3C) usually function as one of the building blocks lined up in tandem to present the ligand-binding V-set domain on the cell surface. This can be seen in many immune receptors such as CD2, CD58,[21] and CD4.[22] There are also many receptors that are exclusively composed of I-set domains, including immune receptor intercellular adhesion molecule-1 (ICAM-1)[23] and neuroreceptors NCAM[24] and Dscam.[25] Thus the I-set variant is the most abundant Ig-like domain and plays a critical biologic role in cell surface receptors.

The Protein Kinase Domain

Protein kinases catalyze the transfer of a phosphate group from adenosine triphosphate (ATP) to specific sites on target proteins. More than 500 protein kinases have been identified in the human genome; approximately 90 of these are tyrosine kinases, the remainder specifically phosphorylate serine or threonine residues. Both serine/threonine and tyrosine kinases share a conserved bilobed protein fold, composed of a smaller N-terminal subdomain (N-lobe) and larger C-terminal subdomain (C-lobe).[26] The active site cleft, including the site for binding the substrate ATP, is found at the interface between the N- and C-lobes. The phosphate-coordinating "P-loop"

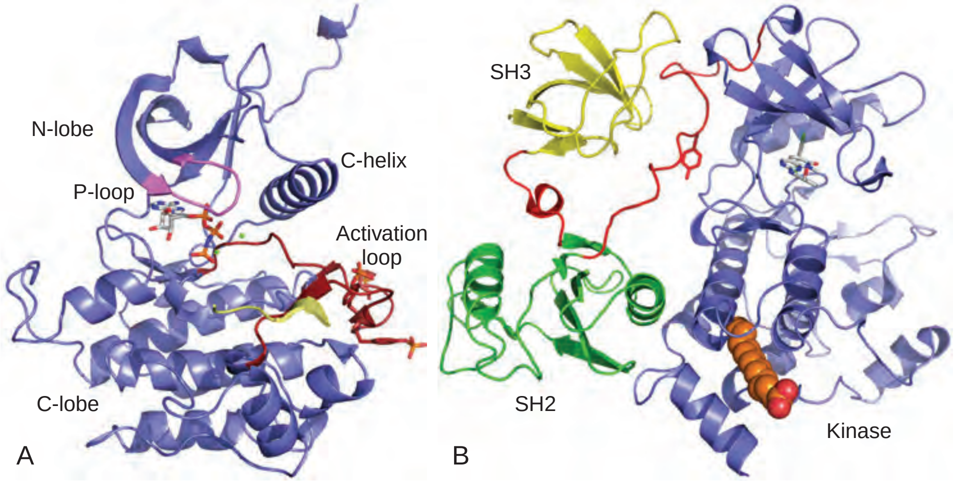

Figure 7.5 (A) A kinase domain in complex with an adenosine triphosphate (ATP) analog and peptide substrate (PDB entry 1IR3). The phosphate-binding loop is highlighted *purple*, the activation loop is *red*, the substrate peptide is *yellow*, and the ATP analog is shown in *gray*. (B) The autoinhibited structure of Abelson tyrosine kinase (c-ABL) in complex with the kinase inhibitor PD166326 (PDB entry 1OPK). The Src homology-3 (SH3), SH2, and kinase domains are shown in *yellow*, *green*, and *blue*, respectively. The SH2–kinase domain linker and the SH3-SH2 connector are shown in *red*. The myristate is shown in *orange* spheres in the C-lobe of the kinase. *PDB*, Protein Data Bank.

is a portion of the β-sheet in the N-lobe that coordinates the triphosphate moiety of ATP. The activity of protein kinases is often regulated by phosphorylation on a loop in the C-lobe termed the activation loop or A-loop. In the absence of phosphorylation, the A-loop may play an inhibitory role, sometimes blocking binding of ATP in the active site, or it may be disordered altogether. Upon autophosphorylation, or phosphorylation in trans by an upstream activating kinase, the activation loop rearranges to adopt a characteristic hairpin conformation that creates the site for docking of the polypeptide segment that will become phosphorylated. Activation loop phosphorylation may also induce other structural rearrangements required for catalytic activation, in particular a reorientation of a helix within the N-lobe (known as the C-helix) that brings a glutamic acid residue into proper position within the active site (Fig. 7.5A).

Deregulated tyrosine kinases are the cause of a number of hematologic malignancies. Two general classes of tyrosine kinases can be defined: receptor and non-receptor tyrosine kinases. Receptor tyrosine kinases are transmembrane proteins with an extracellular ligand–binding domain, a single transmembrane domain, and the cytoplasmic tyrosine kinase domain. They are typically activated by dimerization upon binding of ligands to their extracellular region, which induces autophosphorylation and activation of their catalytic domains inside the cell.[27] Chromosomal translocations that underlie a number of human leukemias fuse a tyrosine kinase domain to an oligomerization domain from an otherwise unrelated protein, often the dimerization domain of a transcription factor, to generate a constitutively dimeric, and therefore constitutively active kinase. Examples of such oncogenic translocations include the fusion of the dimerization domain of an ETS-family transcription factor ETV6 (also called Tel) to a Jak-family tyrosine kinase in the leukemogenic ETV6-Jak2 fusion,[28] and the fusion of the oligomerization domain of nucleophosmin with the tyrosine kinase domain of ALK in the NPM-ALK fusion in anaplastic large cell lymphoma.[29] These translocations are further described in Chapters 57 and 78, respectively.

Perhaps the best characterized kinase translocation is the BCR-ABL fusion protein produced by the (9:22) chromosomal translocation in chronic myelogenous leukemia (see also Chapter 69). Treatment of this disease with imatinib, a specific inhibitor of ABL, has established a paradigm for targeted therapy in cancer.[30] ABL is a non–receptor tyrosine kinase which contains Src-homology 3 and 2 (SH3 and SH2) domains in addition to its tyrosine kinase domain. In addition, the normal ABL protein is myristoylated at its N-terminus. In the normal protein, the N-terminal region including the myristoyl-group and adjacent sequences and the SH3 and SH2 domains assemble with the kinase domain to lock it in an inactive conformation (Fig. 7.5B).[31] These interactions are released to activate the kinase when the phosphotyrosine-binding SH2 domain and proline motif-binding SH3 domains bind their cognate ligands in a target protein.[32] The myristoyl group may also be released from its docking site in the C-lobe of the kinase upon activation to promote membrane localization of the protein. Thus in its normal state, the various domains of ABL comprise an exquisite signaling switch that is regulated by appropriate binding interactions; in the absence of the proper targeting interactions, the kinase is maintained in an inactive state by the intramolecular associations of its domains. In the oncogenic BCR-ABL fusion protein, this regulatory control is lost because the N-terminal regulatory region including the myristoylation site is truncated and replaced with unrelated sequences from the BCR protein. Interestingly, the vacant myristate pocket in BCR-ABL is the target of recently developed allosteric inhibitors of BCR-ABL, which may synergize with ATP-site inhibitors.[33]

High-resolution structural information has facilitated development of selective inhibitors for many tyrosine kinases in addition to BCR-ABL. Prominent examples include ruxolitinib, a Jak1/Jak2 inhibitor that is used to treat myelofibrosis driven by JAK2^{V617F}, and ibrutinib, a Bruton tyrosine kinase (BTK) inhibitor that is used in the treatment of chronic lymphocytic leukemia, mantle cell lymphoma, and Waldenström macroglobulinemia.[34,35] These and other kinase inhibitors are discussed in the chapters covering specific hematologic malignancies.

Membrane Proteins

Membrane proteins account for 20% to 30% of all gene products in most genomes, and they are the targets of 50% of modern drugs.[36] Proteins embedded in or traversing the lipid bilayer mediate exchange of information and materials across membrane barriers. They are architecturally and functionally diverse. Single-pass transmembrane proteins have functional extracellular and/or intracellular domains connected by a single membrane-spanning helix. By contrast, integral membrane proteins typically have much of their mass embedded within the lipid bilayer, with multiple membrane-spanning segments connected by cytoplasmic and extracellular loops. Historically, integral membrane proteins have been difficult to study at a structural level. However, innovations in membrane protein crystallization and protein engineering have made such studies more tractable, allowing elucidation of many important structures at near-atomic resolution.

Most membrane-embedded proteins are predominately helical, although β-strand membrane proteins also occur. Diverse ion channels and GPCRs are integral membrane proteins. One of the largest and most complicated membrane protein complexes characterized to date is that of mitochondrial complex I. This huge proton-pumping machine features 82 transmembrane helices, accounting for approximately half of its molecular mass.[37]

GPCRs are the largest family of membrane proteins—more than 800 have been identified in the human genome. GPCRs mediate fundamental signal transduction processes, touching virtually every aspect of human physiology, from vision, taste, and smell to cardiovascular, endocrine, immunologic, and reproductive functions. Not surprisingly, they represent an important class of drug target. The conserved domain structure of GPCRs includes seven transmembrane helices that pack together across the lipid bilayer. They form a ligand-binding cleft that opens to the extracellular space. The cleft can vary dramatically in size and shape in different GPCRs because some receptors recognize small molecules (e.g., the β_2-adrenergic receptor) whereas others have protein ligands (e.g., chemokine receptors).

Structural studies of the β_2-adrenergic receptor have revealed its mechanism of transmembrane signal transduction via the heterotrimeric G protein $G\alpha_s\beta\gamma$ (Fig. 7.6A).[38] Binding of agonist in the extracellular-facing cleft induces key conformational changes in the cytoplasmic region, in particular a large movement of the sixth transmembrane helix and an extension of the cytoplasmic end of the fifth transmembrane helix (TM5). These alterations promote binding to the Gα-subunit of $G\alpha_s\beta\gamma$. In binding Gα, the agonist-bound receptor functions as a guanine-nucleotide exchange factor (GEF), inducing exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP). GTP-bound Gα dissociates from the βγ heterodimer to activate adenyl cyclase, while the free βγ component signals to Ca^{2+} channels. The inactive and active β_2-adrenergic receptor structures are illustrated in Fig. 7.6A. Currently, at least 70 unique GPCR structures are available, providing substantial impact in drug development.[39]

Membrane proteins can also fulfill catalytic roles, and they operate not only in the plasma membrane but in every lipid membrane in the cell. One example of interest is vitamin K epoxide reductase (VKOR), the target of the anticoagulant drug warfarin (see Chapters 125 and 143). VKOR resides in the endoplasmic reticulum (ER) membrane and catalyzes a key step in the vitamin K cycle—regeneration of vitamin K hydroquinone. This compound is a cofactor for the enzyme that converts glutamic acid residues in the N-termini of vitamin K–dependent clotting factors to γ-carboxy glutamate (Gla) residues. This PTM is required for interaction of these proteins with Ca^{2+} and thus for their function in coagulation. Although the structure of the human enzyme has not been elucidated, the structure of a homologous bacterial protein has been described.[40] In this crystal structure (Fig. 7.6B), the bacterial homolog of VKOR is naturally fused to a thioredoxin (Trx)-like domain, which supplies reducing equivalents. The core of VKOR structure is a four-helix bundle embedded in the membrane (transmembrane helices TM1-TM4, shown in green) with a TM5 linked to the Trx-like domain on the extracellular surface (topologically equivalent to the luminal side of ER-resident mammalian VKOR). The ubiquinone compound has its quinone ring located near the membrane surface with its isoprenyl tail intercalated into the V-shaped cleft between TM2 and TM3. All the enzymatically important residues are on or close to the extracellular side of

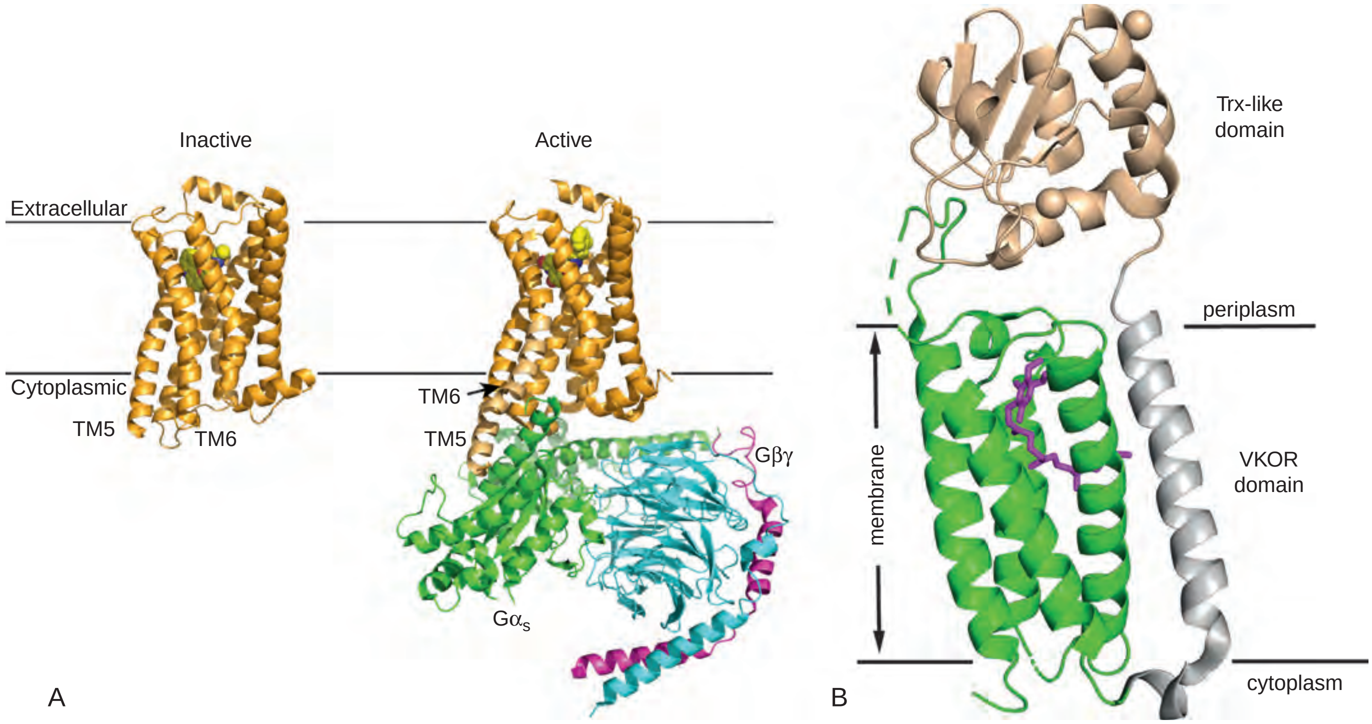

Figure 7.6 MEMBRANE PROTEIN STRUCTURES. (A) Structures of the β_2 adrenergic receptor (β_2AR) in the inactive *(left)* and active *(right)* conformations. Like all G protein–coupled receptors, β_2AR contains seven transmembrane helices. The inactive structure was determined with the antagonist carazolol bound in the ligand-binding site, while the active structure was determined in complex with the tight-binding agonist BI-167107 (ligand are shown as *yellow spheres*). Agonist binding induces conformational changes on the cytoplasmic face of the receptor, including reorientation of the sixth transmembrane helix (TM6) and lengthening of TM5, which in turn promote binding of the heterotrimeric Gαβγ complex. Interactions with the receptor are mediated by the $G\alpha_s$ subunit *(green)*. This interaction induces exchange of guanosine diphosphate for guanosine triphosphate in the $G\alpha_s$ subunit, and promotes dissociation of βγ complex (shown in *cyan* and *magenta* for β and γ, respectively). Illustration is drawn from PDB entries 2RH1 and 3SN6 for the inactive and active structures, respectively. T4 lysozyme fusion partners and a nanobody that was engineered to facilitate crystallization are not illustrated. (B) Structure of a bacterial homolog of the human vitamin K epoxide reductase (VKOR). VKOR is expected to bind vitamin K in a pocket homologous to that formed by four conserved transmembrane helices *(green)* that is occupied by a ubiquinone *(magenta)* in this structure. Warfarin inhibits VKOR by displacing vitamin K from this pocket. See text for further details. Illustration drawn from PDB entry 3KP9. *PDB*, Protein Data Bank.

the membrane, adjacent to the Trx-like domain, providing a plausible path for electron transfer.[40] Interestingly, mapping of mutations that confer resistance to warfarin onto the bacterial structure reveals striking clustering around the ligand-binding pocket, confirming that it is also the site of warfarin binding and that warfarin exerts its inhibitory effect by displacing vitamin K.[40]

FUTURE DIRECTIONS

In this chapter, we have reviewed basic principles of protein structure and introduced a few representative protein folds that recur in proteins of key importance in hematology. Further examples are found throughout the text, reflecting the value of understanding the structural foundations of biologic processes. Structure is key for understanding macromolecular function at a mechanistic level and, by extension, for understanding pathogenic mutations and mechanisms of drug action. Advances in cryo-EM over the past decade promise to bring ever-larger and more complicated proteins and macromolecular complexes into focus.[41] In addition to the TCR complex discussed earlier,[18] single particle cryo-EM has already revealed the molecular architecture of many macromolecular assemblies including the splicesome[42] and the inflammasome.[43] A remarkable time-resolved cryo-EM study of the elongating ribosome yielded 33 distinct states that map the aminoacyl–transfer RNA delivery and proofreading process.[44] Although single-particle studies such as these are carried out with purified macromolecular complexes, cryoelectron *tomography* can provide snapshots of cellular structures in situ at sub-nanometer resolution.[45] A recent application of this technique has revealed the architecture of mammalian primary cilia.[46] In the coming years, we can look forward to an avalanche of new structural and mechanistic insights fueled by these approaches.

Recent advances in computational protein structure prediction promise to provide actionable insights into the structure of proteins for which experimentally determined structures are not available. A remarkably powerful and accurate protein folding engine has been created by combining genetic information (evolutionary covariation derived from multiple sequence alignments of a target of interest) with machine learning tools.[47] Finally, these and other computational tools[48] have enabled de novo protein design.[49] It is now possible to design an entirely novel protein domain with atomic level accuracy and to engineer it to have specific functional properties, such as self-assembly into a higher-order complex or ligand recognition. In the not-too-distant future, we can expect these approaches to open new therapeutic modalities.

CHAPTER 8

PHARMACOGENOMICS AND HEMATOLOGIC DISEASES

Leo Kager and William E. Evans

It is widely recognized that heritable genetic variation (i.e., genotypes or haplotypes) can translate into inherited phenotypes, some of which predispose to or cause diseases and others alter response to treatment. One aim of medical genetics and pharmacogenomics (PGx) is to understand the myriad associations between inherited genotypes and specific phenotypes of disease or drug response, with the ultimate goal of better defining the risk for, or outcome of, diseases and the response to specific medications. In cancer, disease prognosis and treatment response can be affected by both inherited (germline) and acquired (somatic) genome variation, and both types of genome variation have been shown to alter the effects of certain medications. Many seminal discoveries in medical genetics were made in the course of investigating hematologic disorders, with hemoglobinopathies among the most prevalent monogenic disorders, affecting approximately 7% of the world's population. PGx also has a long tradition in hematology; one of the first documented clinical observations of inherited differences in drug effects was the relationship between hemolysis after antimalarial therapy and the inherited glucose-6-phosphate dehydrogenase (G6PD) activity in erythrocytes.[1]

In the pregenomic era, efforts concentrated on mapping highly penetrant monogenic (mendelian) loci for both specific diseases and drug-metabolizing pathways that influence the effects of medications. Completion of the Human Genome Project and the development of arrays for genome-wide single-nucleotide polymorphism (SNP) and DNA methylation analyses, "next-generation" DNA (whole-exome sequencing [WES; coding regions only] and whole-genome sequencing [WGS; coding and noncoding regions]), and RNA sequencing (RNA-seq) technologies have enabled relatively inexpensive and essentially agnostic genome-wide approaches to identify genomic variants that predispose to diseases and/or modify drug responses and/or contribute to heterogeneity of monogenetic disorders and complex diseases that are polygenetic in nature.[2] More recently, single cell sequencing has allowed further resolution of the heterogeneity in genome variation in diseases such as hematologic malignancies. In addition to genome sequence variation, epigenetic differences are increasingly recognized as important for the development of diseases and contribute to differences in the pharmacologic effects of many medications, referred to as *pharmacoepigenomics*.[3] This chapter provides a brief overview of PGx and pharmacoepigenomics, using selected examples to illustrate its current and potential impact on the treatment of hematologic diseases.

VARIATION IN THE HUMAN GENOME

The genome-wide systematic identification of heritable (i.e., germline) and acquired (i.e., somatic) variants, and the functional analysis of genes, their variants, their expression, and their related products (i.e., proteins) have revolutionized the study of many diseases, the development of new medications, and the optimization of drug therapy. Genomics, transcriptomics, methylomics, and metabolomics increasingly enable more comprehensive assessments of a person's risk for acquiring a particular disease, to identify drug targets, and to explain interindividual differences in the effectiveness and toxicity of medications.[1, 2]

The Human Genome Project and subsequent projects such as the International Genome Sample Resource (IGSR) and 1000 Genomes Project (1KGP), and the WGS/Trans-Omics-Precision Medicine (TOPMed) have unveiled many types of variations within the 3.27 billion base pairs (bp) of the human haploid genome (Genome Reference Consortium Human Build 38 patch release 13 [GRCh38.p13]) (Table 8.1); the spectrum ranges from single base-pair differences to large chromosome events, such as insertions or deletions of chromosomal DNA, or structural variants (translocations and other genomic rearrangements that affect more than 50 bp of sequence). For practical purposes, the term *sequence variation* is mainly used herein. *Polymorphisms* are defined as common inherited variations in DNA sequence that are typically, although somewhat arbitrarily, defined as the least common allele having a frequency of 1% or more in the population.

SINGLE-NUCLEOTIDE POLYMORPHISMS

The most common and important inherited sequence variations are SNPs, positions in the genome where individuals have inherited a nucleotide that differs from the most common sequence ("wild-type") at the position in the genome. Many efforts are underway to catalog these variants, because a comprehensive SNP catalog offers the possibility to pinpoint important variants in which nucleotide changes alter the function or expression of a gene that influences diseases or response to medications. The main public database is the "Database of Short Genetic Variations" (dbSNP; a repository of genetic variations less than 50 bp in length) and a growing number of SNPs (currently approximately 135 million validated; dbSNP Build 150) has recently been driven largely by the 1KGP and TOPMed project (see Table 8.1).

SINGLE-NUCLEOTIDE POLYMORPHISMS AND PHENOTYPES

SNPs are present throughout the genome, in exons, introns, promoters, enhancers, and intergenic regions. To elucidate the relationship between SNPs and phenotypes of interest, initial efforts have concentrated mainly on SNPs that are likely to alter the function or expression of a gene. However, only a small portion of the identified SNPs lies within coding regions; only about half of those SNPs cause amino acid changes in expressed proteins, and only a subset of those alters the function of the encoded protein ("damaging SNPs"). SNPs that cause amino acid changes are referred to as *nonsynonymous SNPs* (nsSNPs) and are the main sequence variants underlying most of the highly penetrant inherited monogenic diseases currently known, such as hemoglobinopathies. The likelihood that nsSNPs will result in disease or functional changes in drug metabolism or transport depends on the localization and nature of the amino acid change within the encoded protein; multiple software algorithms have been developed to "predict" whether a certain amino acid change is likely to have a major or minor effect on protein function (i.e., "damaging" versus "nondamaging").

Although it is intuitively obvious that amino acid substitutions have the potential to change the function of a protein, gene expression also can be affected by SNPs positioned in regulatory sequences or intronic regions. For example, a "silent" or synonymous SNP has been identified that affects protein folding and function of an

important drug transporter, namely adenosine triphosphate (ATP)–binding cassette (ABC) transporter ABCB1, and this variant has the potential to influence the intracellular accumulation of drugs that are substrates for ABCB1 (transports some drugs out of cells).[4] Moreover, SNPs in the promoter region can alter the regulatory promoter function and the gene's expression, thereby influencing drug effects. Using a genome-wide association study (GWAS), children and adults who were homozygous for the rs924607 T allele polymorphism in the promoter region of the gene encoding a centrosomal protein involved in microtubule formation *(CEP72)* were found to be significantly predisposed to vincristine-induced peripheral neuropathy, and in vitro experiments have shown that the *CEP72* promoter rs924607 T allele creates a binding site for a transcriptional repressor leading to lower expression of CEP72 messenger RNA (mRNA) and increased sensitivity of neurons and acute lymphoblastic leukemia (ALL) cells to vincristine.[5]

In addition, diverse classes of small to long noncoding RNAs (ncRNAs) have emerged as important regulators of gene expression and genome stability. For example, micro-RNAs (miRNAs) are small (19 to 22 nucleotides), single-stranded RNA molecules that can influence cellular mRNA levels or impair translation after binding to miRNA binding sites at the target gene's 3′-untranslated region. SNPs in miRNA binding sites or in the sequence encoding miRNAs have the potential to alter binding and function of miRNAs, respectively. Indeed, a so-called miRSNP, which is defined as a functional SNP that can interfere with miRNA function, had been reported to affect the expression of the antifolate target dihydrofolate reductase, thereby influencing antifolate pharmacodynamics. The miRNA PGx Database (Pharmaco-miR) is a helpful research resource to identify associations of miRNAs, genes they regulate, and the drugs annotated as being dependent on these genes (see Table 8.1).[6]

Collectively, these examples demonstrate that SNPs in functionally different genomic regions can influence drug disposition and response.

STRUCTURAL GENOMIC VARIANTS

Structural variations are balanced or unbalanced changes in DNA content and encompass alterations ranging from submicroscopic sequence variants greater than 50 bp to larger, sometimes cytogenetically visible, variants. Unbalanced DNA alterations that change the number of base pairs in comparison with a reference genome are as frequent as or even more common than SNPs and include copy number variants (CNVs) or smaller insertions/deletions (indels). Balanced variations such as inversions and translocations are less common in germline DNA but are often found as somatic genome variants in hematologic malignancies (e.g., ALL). Many efforts focus on the identification, validation, and mapping of these variants, and the major catalogs are the Database of Genomic Variants (DGV) and the Database of Human Genomic Structural Variation (dbVAR; see Table 8.1). CNVs are found in a wide spectrum of genomic regions; therefore many pharmacologically relevant genes can be affected by these variants. Indeed, CNVs have been described to influence activity of some of the most important drug-metabolizing enzymes, such as cytochrome P450 enzymes and glutathione *S*-transferases.[7]

SOMATIC GENOMIC VARIANTS

Genomic instability is a hallmark of cancer cells. Nonrandom genetic abnormalities, including aneuploidy (gains and losses of whole chromosomes) and structural rearrangements that often result in the expression of chimeric fusion genes (e.g., *BCR-ABL1*), can be found in the majority of hematologic malignancies. These acquired (somatic) genomic variations can differ significantly from inherited (germline) genomic variations and can, for example, create allele-specific copy number differences between normal host cells and cancer cells. Such differences can have pharmacologically relevant consequences. Indeed, it was shown that the cellular acquisition of additional chromosomes in leukemia cells—for example, the gain of additional chromosomes 21 in hyperdiploid ALL (more than 50 chromosomes)—can cause discordance between germline genotypes and leukemia cell phenotypes, which are important when these discordant genotypes/phenotypes influence the disposition of antileukemic agents. Moreover, somatic deletions of genes encoding proteins that regulate the stability of the DNA mismatch repair enzyme mutS homolog 2 (MSH2) have been identified in approximately 11% of children with newly diagnosed ALL. These deletions in ALL cells have been shown to cause DNA mismatch repair deficiency and increased resistance to thiopurines (TPs), representing another genomic mechanism by which leukemia cells can acquire MSH2 deficiency and mercaptopurine (MP) resistance.[8] In addition, recent comprehensive genomic analyses comparing paired diagnostic and relapsed ALL samples provide evidence for a darwinian selection process of relapse-associated somatic mutations in genes encoding key enzymes involved in antileukemic agent activation/inactivation (e.g., TP resistance due to variants in genes involved in TP inactivation [e.g., *NT5C2* or *PRPS1*], methotrexate [MTX] resistance due to variants in *FPGS* which encodes the cellular MTX activating enzyme folyl-polyglutamyl synthetase, and glucocorticoid (GC) resistance due to variants in the glucocorticoid receptors (GCRs) *NR3C1/2*, and variants in genes encoding epigenetic regulators which affect GC response [e.g., *CREBBP*, and *WHSC1*]) during disease progression.[9]

CATALOGS OF GENOMIC VARIANTS, GENOTYPING PLATFORMS, AND GENOME-WIDE ASSOCIATION STUDIES

Cataloging the pattern of genome variation in diverse populations is fundamental in understanding areas of human phenotypic diversity such as interindividual and interethnic differences in drug responses; increasingly detailed maps of human genomic variation are provided in public databases (see Table 8.1). Information from these maps has been used to design high-throughput genotyping platforms (e.g., SNP chips), thereby providing tools to interrogate the relationship between genetic variation across the human genome and important phenotypes such as disease or response to medications in a relatively unbiased (agnostic) fashion.[2]

SNP catalogs have been used in GWASs to pinpoint genes important to diseases and drug responses, and approximately 10% of published GWAS have focused on PGx. International consortia like the Pharmacogenomics Research Network–RIKEN Global Alliance (PGRN-RIKEN) were established to facilitate GWAS PGx studies,[10] and a publicly available resource—the National Human Genome Research Institute–European Bioinformatics Institute (NHGRI-EBI) GWAS Catalog—provides an updated summary of published GWASs (see Table 8.1).

Variation in the Human Epigenome

Epigenetics encompasses inherited and acquired changes in gene function that cannot be explained by alterations in sequence of nucleic acids. The epigenome is a complex layer of regulatory information that is superimposed on the genome (*epigenetics* literally means "above genetics"), with major mechanisms that contribute to epigenetic variation including DNA methylation, DNA hydroxymethylation, and various histone modifications such as histone acetylation and methylation. As in medical genetics, many seminal discoveries in medical epigenetics were made during investigations of hematologic diseases, and the myelodysplastic syndrome is considered a prototypical example of an epigenetic disease. In contrast to stable sequence variants, the epigenetic cellular state is principally malleable and can be influenced by environmental factors such as diet and toxin exposure. Of note, the expression of genes that encode important drug-metabolizing enzymes (e.g., cytochrome P450) and drug transporters (e.g., solute carrier [SLC] family) have been shown to be altered via intrinsic and extrinsic factors that modify the epigenetic signature, thereby influencing the disposition and effects of drugs.[3] Moreover, the dynamic nature of epigenetics provides a mechanism to modulate the expression of genes that influence drug sensitivity, and so-called epidrugs (i.e., drugs that influence gene expression via epigenetic mechanisms) have already been successfully incorporated into the treatment of hematologic diseases (e.g., hypomethylating agents such as decitabine and azacitidine for myelodysplastic syndrome, and histone deacetylase inhibitors (HDACis) such as vorinostat for acute myeloid leukemia [AML], belinostat for T-cell lymphoma and romidepsin for cutaneous T-cell lymphomas).[3]

Efforts are ongoing to generate detailed epigenomic maps to provide a basis for understanding cellular processes, the pathogenesis of diseases, and alterations in drug responses, such as the Encyclopedia of DNA Elements (ENCODE) and the Epigenomics Roadmap (see Table 8.1).

GENETIC VARIATIONS INFLUENCING DRUG RESPONSE: PHARMACOGENETICS–PHARMACOGENOMICS–PHARMACOEPIGENOMICS

PGx is a major element of the Precision Medicine Initiative announced by US President Barak Obama in 2015. Currently, empiric approaches are typically used to select drug therapy for most patients and most diseases, despite the fact that there is great heterogeneity in the way people respond to medications, in terms of both host toxicity and treatment efficacy. Unfortunately, for almost all medications, interindividual differences are the rule, not the exception, and these differences result from the interplay of many variables, including genetics and environment. Variables influencing drug response include pathogenesis and severity of the underlying disease being treated; drug interactions; the patient's age, sex, nutritional status, and renal and liver function; the presence of concomitant illnesses; and other components of treatment. In addition to these clinical variables, both inherited and acquired (e.g., somatic mutations in cancers) genome variation can influence the disposition and effects of medications, including many used to treat hematologic diseases. Clinical observations of inherited differences in drug effects (based on family studies and twin studies) were first documented in the 1950s, and the concept of pharmacogenetics was defined initially in 1959 by Friedrich Vogel as "the study of the role of genetics in drug response." The number of recognized clinically important pharmacogenetic traits grew steadily in the 1970s; the elucidation of the molecular genetics underlying these traits began in the late 1980s and 1990s, with their translation to molecular diagnostics to guide drug therapy being well underway in the 2000s. The study of pharmacogenetics began with the analysis of genetic variations in drug-metabolizing enzymes and how those variations translate into inherited differences in drug effects. Subsequently, the field has incorporated genome-wide approaches to identify networks of genes that govern the clinical response to drug therapy (i.e., PGx). However, the terms *pharmacogenetics* and *PGx* are generally considered to be synonymous for all practical purposes. With the recognition that epigenetic modification affects gene expression and can contribute to variability in drug effects, the field of pharmacoepigenomics has gained additional attention and importance.

Overall, PGx can be viewed as a broad strategy to establish models of drug disposition and effects by integrating information from genome sequencing, functional genomics, high-throughput molecular analyses, pharmacokinetics (e.g., drug metabolism and disposition), and pharmacodynamics (treatment response, adverse drug reactions [ADRs]). Approaches to establish PGx models include candidate gene analyses (which focus on the analysis of single genes or sets of functionally related genes in pathways thought to be important for the medicine under study) and more agnostic genome-wide analyses. PGx models can be used to maximize efficacy and reduce toxicity of existing medications and to identify novel therapeutic targets.

Comprehensive reviews on PGx and pharmacoepigenomics are available elsewhere.[1–3] Herein, clinically relevant examples are provided to illustrate the potential of PGx and pharmacoepigenomics to improve current drug therapy for hematologic disorders, to prevent hematologic toxicity, and perhaps to identify novel targets for developing new therapeutic approaches in hematology.

OPTIMIZATION OF DRUG THERAPY

Drug effects are typically determined by the interplay of several gene products that influence the pharmacokinetics and pharmacodynamics of medications. Pharmacokinetics entails characterization of the absorption, distribution, metabolism, and excretion (ADME) of medications. Pharmacodynamics is the relationship between the pharmacokinetic properties of drugs and their pharmacologic effects, either desired or adverse. The ultimate goals of PGx and pharmacoepigenomics in this context are to elucidate the inherited determinants for drug disposition and response to select medications and dosages on the basis of each patient's inherited ability to metabolize, eliminate, and respond to specific drugs. A model of how polygenic variables can determine drug response is illustrated in Fig. 8.1.

GENETIC VARIATIONS THAT INFLUENCE DRUG DISPOSITION AND EFFECTS

Drug Metabolism and Effects

There are many enzymes involved in drug metabolism, which are often categorized into phase I reactions that involve oxidation, reduction, or hydrolysis of medications, and phase II enzymes that conjugate drugs via acetylation, glucuronidation, sulfation, or methylation. Although phase I metabolism often inactivates medications, this is not always the case, as exemplified by codeine's activation by cytochrome P450 CYP2D6 and clopidogrel's activation via CYP2C19. Phase II conjugation generally makes medications more water soluble and therefore more readily excreted in the urine, but some phase II conjugates have pharmacologic effects. Although the liver is generally considered the central organ for drug metabolism involved in the clearance of approximately 70% of drugs, phase I and II metabolic enzymes are found in many other tissues, including the kidney, intestinal tract, lung, brain, spleen, erythrocytes, and lymphocytes.

Essentially all genes encoding drug-metabolizing enzymes with more than 30 families of enzymes in humans exhibit genetic variation, many of which translate into functional changes in the proteins encoded. Inheritance of genes containing sequence variations that alter the function of enzymes they encode, as well as CNVs or epigenetic signatures that alter the expression of functionally relevant genes, can influence either drug activation or inactivation and ultimately determine the extent of drug effects. This is most evident when polymorphic genes encode enzymes that are involved in crucial pathways of elimination or activation of the administered medication. It should also be recognized that genetic polymorphism in genes that encode the protein targets of medications (e.g., VKORC1, the target of warfarin) can also have a significant influence on drug effects.

The focus of this chapter is to provide examples that are relevant to hematologists to illustrate the potential impact of genome variation on the effects of medications. We discuss PGx mechanisms involved in toxicity and/or drug resistance of the antileukemic and immunosuppressive TPs and GCs as well as variants in the gene encoding the enzyme (CYP2C9) that metabolizes (inactivates) warfarin and variants in the gene that encodes warfarin's target (VKORC1). These examples therefore involve both phase I (CYP2C9) and phase II (TP *S*-methyltransferase [TPMT]) drug-metabolizing enzymes and the target of a still widely prescribed anticoagulant. Our examples include both inherited genome variations (*CYP2C9, TPMT, NUDT15*, and *VKORC1*) and somatically acquired genomic and epigenomic variants (*NT5C2, PRPS1, CASP1, NLRP3*, and *CELSR2*) that have been shown to alter drug effects in humans. This is a rapidly evolving component of "precision medicine," thus providing an understanding of their relevance and potential is of greater value than attempting a current and comprehensive literature review.

Pharmacogenomics of Thiopurines in Childhood Leukemia

As prodrugs, the TPs MP (major treatment component in lymphoid malignancies) and thioguanine (TG; treatment component

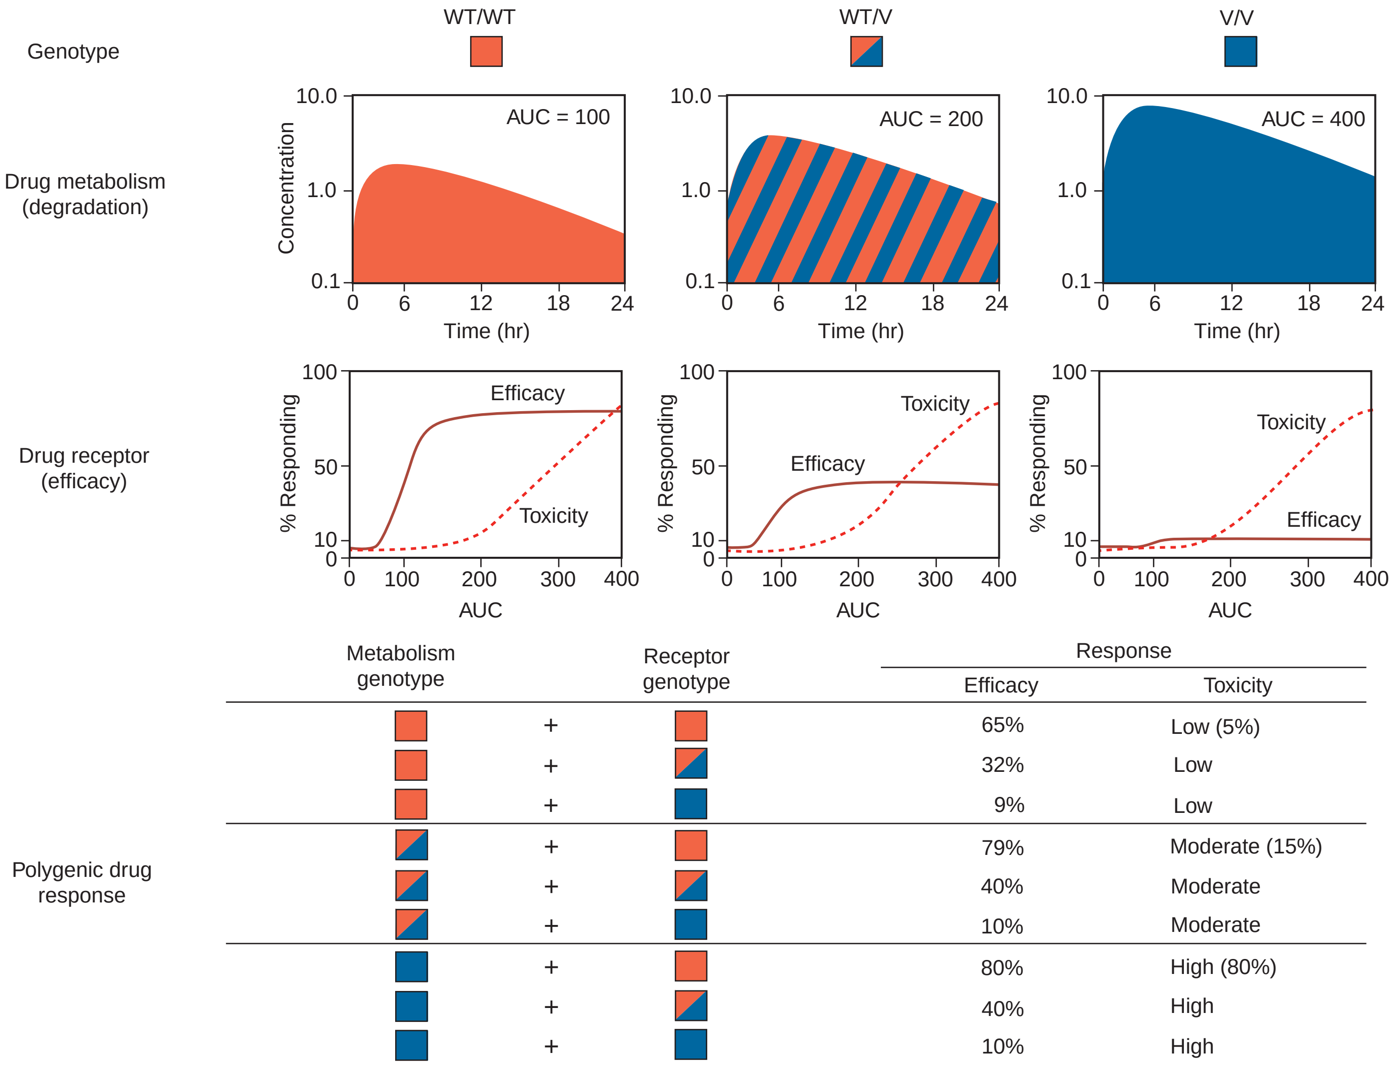

Figure 8.1 POLYGENIC DETERMINANTS OF DRUG RESPONSE. The potential effects of two genetic variants are illustrated. One genetic variant involves a drug-metabolizing enzyme *(top)*, and the second involves a drug receptor *(middle)*. Differences in drug clearance (or the AUC) and receptor sensitivity are depicted in patients who are either homozygous for the wild-type allele (WT/WT) or heterozygous for one wild-type and one variant allele (WT/V) or have two variant alleles (V/V) for the two genetic variants. At the bottom are shown the nine potential combinations of drug metabolism, drug-receptor genotypes, and the corresponding drug-response phenotypes, which were calculated with data from the top. The therapeutic indexes (efficacy-to-toxicity ratios) ranged from 13 (65%:5%) to 0.125 (10%:80%). *AUC*, Area under the plasma concentration–time curve; *V*, variant; *WT*, wild-type. *(Courtesy Evans WE, McLeod HL. Pharmacogenomics: drug disposition, drug targets, and side effects. N Engl J Med. 2003;348:538. Copyright 2003 Massachusetts Medical Society. All rights reserved.)*

in myeloid malignancies) are metabolized by numerous enzymes, either to activate TPs to thioguanine nucleotides (TGNs) or to inactivate TPs via methylation or dephosphorylation of TGNs. Although there is genetic polymorphism in enzymes involved in TP activation (e.g., hypoxanthine phosphoribosyltransferase 1 [HPRT1]), there is little evidence that genetic polymorphisms in these enzymes play an important role in controlling the pharmacologic effects of TPs, with the exception of patients who inherit HPRT1 deficiency, an X-linked disease that occurs in approximately 1 in 350,000 males of European ancestry (Lesch–Nyhan syndrome), because these patients cannot activate TPs. In contrast, genetic polymorphisms in two enzymes involved in the inactivation of TPs increase the accumulation of their active TGNs, thereby increasing the risk of hematopoietic toxicity; TPMT and NUDT15 (nucleoside diphosphate linked moiety X-type motif 15 or nucleotide triphosphate diphosphatase). Inherited variants in TPMT were first discovered in the 1990s, with two major inactive variant alleles accounting for the majority of inherited TPMT deficiency in major world populations studied to date (*TPMT*3C* is the most common variant allele in persons of Asian and African ancestry, and *TPMT*3A* in persons of European ancestry). *TPMT*3A*, *TPMT*3C*, and a third variant *TPMT*2* account for more than 95% of the clinically actionable TPMT variants. Variant *TPMT* alleles encode unstable proteins, and each named star *(*)* allele is defined by a certain genotype (haplotype) at one (e.g., *TPMT*2* [rs1800462] and *TPMT*3C* [rs1800460]) or more (e.g., *TPMT*3A* [rs1142345 and rs1800469]) specific loci and is associated with a lower level of enzyme activity (the star *[*]* nomenclature system provides a “common language” to name a growing number of variants being discovered; however, attempts are being made to implement the conventional “rs” designation). The *TPMT*1* allele encodes the wild-type normal function allele, and individuals who carry *TPMT*1/*1* alleles are named “normal metabolizers” (for details see the website of the Clinical Pharmacogenetics Implementation Consortium [CPIC])[11] (see Table 8.1). Patients who are heterozygous (e.g., *TPMT*1/*2*,

TABLE 8.2 **CPIC Recommendations on Medications Whose Adverse Effects Have Been Associated with Variability in Candidate Genes and Manifest Predominantly as Hematologic Abnormalities**

Adverse Drug Reaction	Drug(s) That Cause ADR	Important Genetic Variant(s)	CPIC Recommendation
Myelosuppression	6-Mercaptopurine 6-Thioguanine azathioprine	*TPMT*2* (rs1800426), **3A* (rs1800460 + rs1142345), **3C* (rs1142345) *NUDT15*2* (rs116855232+rs869320766), *NUDT15*3* (rs116855232)	*Poor metabolizers:* Start with drastically reduced doses (reduce daily dose by 10-fold and dose thrice weekly instead of daily) and adjust doses of thiopurines based on degree of myelosuppression and disease-specific guidelines. Allow 4–6 weeks to reach steady-state after each dose adjustment. If myelosuppression occurs, emphasis should be on reducing thiopurines over other agents. For nonmalignant conditions, consider alternative immune-suppressants. *Intermediate metabolizers:* see Ref. 11
Bleeding risk	Clopidogrel	*CYP2C19*17* (rs12248560)	Recommends an alternative antiplatelet therapy (e.g., prasugrel, ticagrelor) for poor or intermediate CYP2C19 metabolizers if there is no contraindication
Myelosuppression (mucositis, neurotoxicity)	5-Fluorouracil (5-FU)	Dihydropyrimidine dehydrogenase: *DPYD*2A* (rs3918290), **13* (rs55886062), *DPYD* rs67376798 A (on the positive chromosomal strand)	For fluoropyrimidines (i.e., 5-FU, capecitabine, or tegafur) recommends an alternative drug for patients who are homozygous for *DPYD* nonfunctional variants, as these patients are typically DPD deficient. Consider a 50% reduction in starting dose for heterozygous patients (intermediate activity)
Bleeding risk	Warfarin and other coumarin derivatives	*CYP2C9*2* (rs1799853), *CYP2C9*3* (rs1057910), *VCORC1* (rs9923231)	The best way to estimate the anticipated stable dose of warfarin is to use the algorithms available on http://www.warfarindosing.org
Acute hemolytic anemia	Rasburicase and other drugs (see Refs. 31 and 33 for a full list of drugs)	Deficient or deficient with chronic nonspherocytic hemolytic anemia (CNSHA). A male carrying a class I, II, or III allele, a female carrying two deficient class I–III alleles (see text for more details)	Rasburicase is contraindicated in G6PD-deficient patients with or without CNSHA. In patients with a negative or inconclusive genetic test results an enzyme activity test is recommended prior to rasburicase treatment to determine whether a patient is G6PD deficient; alternatives include allopurinol

CPIC, Clinical Pharmacogenetics Implementation Consortium. For CPIC website, see Table 8.1.

**1/*3A*, or **1/*3C* alleles, so-called intermediate metabolizers, 5% to 10% of Europeans or Africans) are approximately 5 times more likely to develop hematologic toxicity, whereas patients who inherit two variant alleles (e.g., the alleles *TPMT*3A/*3A, *2/*3A, *3A/*3C*, or **2/*3C*, so-called poor metabolizers, 1 in 300 persons of European or African ancestry) will all develop hematologic toxicity if treated with conventional doses of TPs.[11]

It has been recognized for many years that patients of Asian ancestry develop more hematologic toxicity than patients of European or African ancestry, yet the frequency of nonfunctional *TPMT* alleles is lower in Asians. Important new insights were initially provided in 2014 by the identification of a missense variant in *NUDT15* (nsSNP rs116855232, c.415C>T causing p.R139C) in South Korean patients with inflammatory bowel disease who developed hematologic toxicity while receiving azathioprine therapy.[12] *NUDT15* encodes a nucleoside diphosphatase which catalyzes the conversion of cytotoxic thioguanine triphosphate (TGTP) metabolites to the less toxic thioguanine monophosphates (TGMP). In vitro studies showed that the p.R139C change leads to nearly complete loss of NUDT15 enzymatic activity due largely to protein instability.[13] Loss-of-function variants in *NUDT15* result in higher levels of cytotoxic TGTPs, which are incorporated into DNA (i.e., DNA-TGs), leading to apoptosis, resulting in antileukemic and myelotoxic effects. Like for *TPMT*, other rare variants have been discovered and functionally characterized in *NUDT15*.[14] However, the p.R139C variant is the most common and clinically actionable and can be observed either alone (*NUDT15*3* allele) or together with the p.V18_V19dup (rs869320766; c.50_55dup) variant as a distinctive haplotype (*NUDT15*2* allele).[11] In a GWAS of children with ALL from diverse ethnic backgrounds receiving MP maintenance therapy, both *TPMT* (20%) and *NUDT15* (22%) were estimated to account for 42% of interpatient variability in MP tolerance; 80% of patients with severe myelosuppression during MP therapy had risk alleles of either one of these genes.[15] Together, these studies show that genetic polymorphisms in both of these genes influence TP tolerance and that *TPMT* variants are more common in patients of European and African ancestry, whereas *NUDT15* variants are much more common in East Asians and Hispanics with high levels of Native American ancestry.[15] The CPIC guidelines for dosing TPs now incorporate both *TPMT* and *NUDT15* (see box on MP Dosage Adjustment and Table 8.2).[11]

In addition, it was recently discovered that acquired somatic mutations in *NT5C2* (encoding 5′-nucleotidase, cytosolic II) and in *PRPS1* (encoding ribose-phosphate pyrophosphokinase 1) are relatively common in ALL cells at the time of disease relapse, conferring resistance to TP.[16, 17] The mechanisms by which each of these genetic polymorphisms or somatic variants influence the pharmacologic effects of TP medications in children with ALL and the appropriate dosage adjustments for such patients are discussed in greater detail in the box on MP Dosage Adjustment and in the following section.

Relapse of Acute Lymphoblastic Leukemia, Thiopurine Resistance, and Somatic Variants in *NT5C2* and *PRPS1*

In 1988 Pieters and Veerman published a “breakdown hypothesis” to explain TP resistance in leukemia; that is, leukemic cells are resistant to MP and TG because of the breakdown of the toxic trinucleotide form of TPs (i.e., TGNs) into the nontoxic nucleoside form by cytosolic 5′ nucleotidase. This hypothesis was verified 25 years later, when two study groups explored molecular mechanisms for drug resistance in childhood ALL, by sequencing

MP DOSAGE ADJUSTMENT ACCORDING TO THE CPIC GUIDELINES BASED ON *TPMT* AND *NUDT15* GENOTYPES IN ACUTE LYMPHOBLASTIC LEUKEMIA

MP is a mainstay of treatment of childhood ALL. However, the conventional starting dose of 75 mg/m^2/day of this prodrug can induce severe myelotoxicity in patients who have impaired TP metabolism in hematopoietic tissues, owing to less stable TPMT enzyme variants or loss of activity NUDT15 enzyme variants. The three major variant alleles in *TPMT* (*TPMT*2*, *TPMT*3C*, and *TPMT*3A*) and the two major variant haplotypes in *NUDT15* (*NUDT15*2* and *NUDT15*3*) encoding the variant proteins can quickly be determined by certified clinical laboratories (Genetic Testing Registry [GTR]; see Table 8.1) using samples obtained from peripheral blood before MP therapy. In TPMT poor metabolizers (TPMT-PMs; ~1 out of 300 Europeans and Africans), starting with drastically reduced MP doses (i.e., 10-fold reduction of conventional dose and reduction of frequency to thrice weekly instead of daily) is recommended. In TPMT intermediate metabolizers (TPMT-IMs; 5% to 10% of Europeans and Africans), the MP starting dose should be reduced to 30% to 80% of normal dose if the starting dose is 75 mg/m^2/day or greater. If the starting dose is already less than 75 mg/m^2/day, upfront dose reduction may not be necessary in TPMT-IMs.

An MP starting dose of 10 mg/m^2/day is recommended for NUDT15 poor metabolizers (NUDT15-PMs; 1 in 50 patients from East Asian descent). For NUDT15 intermediate metabolizers, MP dosing recommendations are the same as for TPMT-IMs.[11]

the transcriptomes and whole exomes of diagnostic, remission, and relapse samples from ALL patients.[16,18] In B-cell ALL up to 10% and in T-cell ALL up to 19% of the relapse samples had mutations in the *NT5C2* nucleotidase. The NT5C2 nucleotidase physiologically regulates the cellular purine nucleotide pool and can inactivate the cytotoxic forms of MP and TG (i.e., TGNs). To date, 32 *NT5C* mutant alleles have been described with *NT5C2* R367Q being the most common relapse-associated variant, accounting for 90% of mutant causes.[19] Of note, the relapse-associated variants in *NT5C2* increased the enzyme activity of the variant proteins (up to 48-fold), thereby protecting ALL cells against TP-induced apoptosis, by cleaving the phosphate molecules, preventing incorporation into DNA. Maintenance therapy with the antimetabolites MP and MTX is an essential component of successful ALL therapy, and one can speculate that resistance to MP can give rise to early relapse of ALL. Indeed, a significant association of activating *NT5C2* variants and early ALL relapse was found.[16, 18] Moreover, ALL clones harboring *NT5C2* mutations seem not to be present at diagnosis of ALL but rather are emerging and selected for in a darwinian process (i.e., cellular competition and chemotherapy may act as dynamic evolutionary forces shaping the clonal architecture of ALL relapse) during antimetabolite-based maintenance therapy.[19] Novel strategies are necessary to overcome this drug resistance phenotype in the subset of patients with *NT5C2* activating mutations, and such strategies may help to further improve outcome in ALL by avoiding inappropriate drug levels at the target site (e.g., by using drugs that are not inactivated via NT5C2 or by design of small molecules that inhibit NT5C2 function). However, caution must be noted in the context of small molecule NT5C2 inhibition, because germline homozygous loss-of-function variants in *NT5C2* cause a severe neurologic syndrome (i.e., spastic paraplegia 45), and thereby such inhibitors may have neurotoxic adverse effects.

Likewise to the emergence of *NT5C2* mutant clones, also the emergence of clones with mutations in another important mediator of TP metabolism, namely variants in *PRPS1* (encoding phosphoribosyl pyrophosphate synthetase 1), were more recently identified in children with relapsed ALL.[17] Activating *NT5C2* mutations directly affect the degradation of active TGNs, whereas mutations in *PRPS1* can indirectly impair metabolism and activation of TGs by causing defects in the purine salvage pathway.[17] Like activating variants in *NT5C2*, *PRPS1* mutations seem not to originate from a preexisting clone but rather arise during ALL therapy. The drug resistance phenotype deregulating de novo purine synthesis in relapsed ALL harboring *PRPS1* variants may be overcome by inhibition of this upregulated pathway. Indeed, lometrexol, an inhibitor of de novo purine synthesis, effectively abrogated PRPS1 mutant-driven TP resistance in vitro and may be a therapeutic option in this subset of patients with ALL relapse.

Glucocorticoid Pharmacogenomics in Childhood Acute Lymphoblastic Leukemia

GCs are a major component of successful ALL therapies, and leukemia cell resistance to GCs (assessed either in vitro or in vivo) confers a poor prognosis. As steroid hormones, GCs bind to the GCR (encoded by the nuclear receptor subfamily 3 gene [*NR3C1*]), and this leads to translocation of the receptor into the nucleus, where it acts as a transcription factor and binds to GC response elements triggering the activation or repression of gene transcription, which ultimately results in diminished proliferative capacity and apoptosis of ALL cells.

GC therapy can be associated with severe ADRs with sometimes debilitating consequences. For example, adolescent females are at highest risk for an epiphyseal arteriopathy leading to avascular osteonecrosis (AVN), which often necessitates early joint replacement. Although several PGx investigations were designed to identify predictors of AVN, besides sex and age, no clinically actionable predictors have been identified to date. Unlike the situation in TP myelotoxicity where *TPMT* and *NUDT15* have been proven as clinically actionable common genetic variants with large effect sizes, GC-induced AVN might be mediated by numerous rarer variants with small effect sizes, necessitating more complex models.

In parallel to the situation in ADRs, GC resistance of leukemia cells has also been identified to be rather polygenic in nature. In integrated genomic and epigenomic investigations in primary ALL cells and in vitro model systems, dysregulation of key components (i.e., caspase 1 encoded by *CASP1*, and its activator NLR family pyrin domain containing 3 encoded by *NLRP3*) of the so-called NALP3 inflammasome pathway—which cleaves and inactivates the GCR NR3C1—were identified as a novel GC resistance mechanism.[20] Reduced somatic promotor methylation in *CASP1* and *NLRP2* was found in ALL cells resistant to GCs, leading to an increase of transcription and translation of *CASP1* and *NLRP3*, resulting in higher mRNA and protein levels of CASP1 and NLRP3 and enhanced caspase1 cleavage and inactivation of the GCR.[20] This discovery opens several avenues for further action (e.g., prospectively screen childhood ALL samples for *CASP1* and *NLRP3* expression to alter treatment in patients whose leukemia cells carry these variants and to search for small molecule inhibitors of CASP1), although there are no known caspase1 inhibitors approved for clinical use (e.g., VX-765 or VRT-0431198 are preclinical candidates).

Moreover, in a GWAS on diagnostic and relapsed ALL samples, variants in *NR3C1*/*NR3C2* (encoding the GCRs), in *CREBBP* (encoding the histone lysine acetyltransferase CREB binding protein), and in *NSD2* (encoding the nuclear receptor binding SET domain protein 2) were found to be significantly enriched or exclusively present in relapse; variants in these genes have been identified previously to be implicated in GC resistance.[9] Monitoring for these and other drug resistance/relapse-associated mutations (e.g., variants in *NT5C2*, *PRPS1*, or *MSH2*) may help to early identify emergence of a TP- or GC-resistant ALL cell clone; such patients may then benefit from the introduction of other therapies, such as the proteasome inhibitor bortezomib or, if the ALL is of B-cell origin, from CD19-targeting immunotherapies such as chimeric antigen receptor (CAR) T cells or a bispecific antibody therapy with blinatumumab, or CD22-targeting therapy with inotuzumab ozogamicin (InO).

More recently, it was discovered that approximately 50% of GC-resistant ALL have low expression of the G protein–coupled receptor CELSR2. Downregulation of CELSR2 was associated with reduced expression of the GCR and with increased expression of the antiapoptotic protein BCL2 after GC treatment, and preclinical studies showed that the BCL2 inhibitor venetoclax can mitigate this form of GC resistance in ALL.[21]

Inherited Genome Variants in Cytochrome P450 Enzymes

The cytochrome P450 (CYP) superfamily is a system of phase I enzymes involved in the metabolism of endogenous substances and exogenous compounds (e.g., drugs, environmental chemicals). In humans the CYP enzymes are encoded by more than 57 genes, and the majority of these genes are polymorphic. Updated information regarding the nomenclature and properties of the variant alleles with links to the rs numbers/dbSNP identifiers is available at the website of the Pharmacogene Variation Consortium (PharmVar.org) (see Table 8.1).

On the basis of patient genotype (diplotype) CYP variant alleles, individuals are often categorized into one of four major predicted drug metabolism phenotypes: poor metabolizers (having two loss-of-function alleles), intermediate metabolizers (being deficient in one allele), extensive metabolizers (having two copies of functional alleles), and ultrarapid metabolizers (having three or more functional gene copies due to gene duplications, or two increased-activity alleles, or one functional allele plus one increased-activity allele).

Different populations of metabolizers have been linked to different types of variants in the coding region of CYP genes (i.e., SNPs that alter the amino acid encoded, thereby altering protein function or stability); SNPs in intronic regions, which can alter CYP gene mRNA expression; CNVs (e.g., gene deletions, gene duplications) of CYP genes; or differences in the methylation at CpG islands in promoter and 5′ regions, which alter expression of CYP genes.

Many pharmacologically relevant variants in CYP genes have been identified. The focus here is on the variants in *CYP2C9*, which have been shown to influence the metabolism of an extensively prescribed medication: warfarin.

Pharmacogenomics of Warfarin

The oral vitamin K antagonist warfarin is still used to prevent thromboembolic events in patients with chronic conditions such as atrial fibrillation (AF). A narrow therapeutic index with a risk for serious hemorrhage and interindividual variability in response to warfarin necessitate individualization of treatment, which has been based primarily on monitoring prothrombin time via international normalized ratio (INR) testing. Compared with the therapeutic INR range (i.e., 2 to 3), an INR greater than 4 is associated with a 25-fold higher risk of bleeding in elderly patients treated with warfarin, and the percentage time in therapeutic range (PTTR) is a widely accepted read-out for treatment effect. Complications from inappropriate warfarin dosing remain among common reasons for hospitalization due to ADRs.

Pharmacologically, warfarin is a racemic mixture of *R*- and *S*-enantiomers that differ in their patterns of metabolism and in their potency of pharmacologic effects, with *S*-warfarin being more potent. Warfarin dose requirements can be influenced by both modifiable (e.g., compliance, dietary vitamin K intake, therapeutic level surveillance) and nonmodifiable factors (e.g., age, gender, genetics). Candidate gene studies initially demonstrated that the *CYP2C9* genotype influences warfarin clearance and alters oral anticoagulant dose requirements and bleeding risks. CYP2C9 is the principal CYP2C isoenzyme in the human liver, and it is involved in the oxidative metabolism and inactivation of *S*-warfarin.[22]

The two most common *CYP2C9* variants with diminished enzyme activities are *CYP2C9*2* (c.430 C>T, p.Arg144Cys, rs1799853) and *CYP2C9*3* (c.1075 A>C, p.Ile359Leu, rs1057910). Approximately 35% of Caucasians have one or two of these variant alleles; the **2* and **3* variants are virtually nonexistent in Africans and Asians (95% express the wild-type genotype [i.e., extensive metabolizers]).

Compared with the wild-type genotype (*CYP2C9*1/*1*), patients with two nonfunctional variants have a reduction of enzyme activity to approximately 12% for *CYP2C9*2/*2* and approximately 5% for *CYP2C9*3/*3*. Therefore the required dose of warfarin is lowest in homozygous carriers of the *CYP2C9*3* variant and intermediate in homozygote carriers of the *CYP2C9*2* variant.[22]

An important finding was the identification of an additional mechanism underlying warfarin resistance in 2004—the discovery of sequence variants in the warfarin target gene *VKORC1*, which encodes the vitamin K epoxide reductase complex 1. This complex regenerates reduced vitamin K for another cycle of catalysis, which is essential for the posttranslational γ-carboxylation of vitamin K–dependent clotting factors. A common noncoding variant (−1639G>A, rs9923231) was shown to be significantly associated with warfarin dose requirements. Patients with the −1639 AA genotype require lower initial warfarin doses when compared with individuals with the −1639 GG variant. As the −1639G>A polymorphism affects a VKORC1 transcription factor binding site, the functional effect of the variant is thought to be related to decreased VKORC1 transcription, leading to lower protein expression. There are major differences in the distribution of VKOCR1 haplotypes among ethnic groups, and this may explain interethnic differences in coumarin requirement.[22] GWAS in patients treated with warfarin showed two major signals in and around *VKORC1* and *CYP2C9* and identified a much weaker association with *CYP4F2*. The CYP2F4 enzyme catalyzes vitamin K oxidation and the *CYP4F2*3* variant (c.1297 G>A, p.Val433Met, rs2108622) was identified to require increased warfarin dosing. Overall, *VKORC1* explains approximately 25% of the variance in coumarin dose requirement, *CYP2C9* explains approximately 15%, and *CYP4F2* explains approximately 2%.[22]

In 2010 the US Food and Drug Administration (FDA) updated the label on warfarin, providing *VKORC1* and *CYP2C9* genotype-specific ranges of doses, and suggested that *VKORC1* and *CYP2C9* genotypes be taken into consideration when the drug is prescribed. In addition, dosing algorithms are available online, including genetic and nongenetic information that can help to optimize the warfarin starting dose (see CPIC Guidelines and Table 8.2).[22]

Three large randomized controlled trials (RCTs) have prospectively evaluated the benefit of genotype-guided warfarin dosing. The European Pharmacogenetics of Anticoagulant Therapy (EU-PACT; ClinicalTrials.gov number, NCT01119300) trial demonstrated that PGx-guided dosing is superior to a fixed-dosing regimen for achieving therapeutic INRs, whereas the US Clarification of Optimal Anticoagulation through Genetics (COAG; NCT00839657) study failed to demonstrate an improvement in PTTR with genotype-guided dosing compared with the algorithm-guided dosing control arm. Potential reasons for the differences include differences in the algorithmic strategies and control arms, as well as ancestry-related differences in the nature of variant VKORC1 alleles. The Genetic Informatics Trial (GIFT; NCT01006733) of warfarin to prevent deep venous thrombosis included 1597 patients after knee or hip arthroplasty; and the rate of a composite risk of major bleeding, INR of 4 or greater, venous thromboembolism (VTE), or death was reduced in the genotype-guided warfarin dosing arm compared with clinically guided dosing arm.

Alternative anticoagulants (e.g., the four direct oral FXa inhibitors dabigatran, apixaban, rivaroxaban, and edoxaban which are not influenced by the same polymorphisms as warfarin) have been developed, and there was a major shift toward the use of these drugs (e.g., apixaban was the second highest selling drug with 9.8 billion dollars in 2018) because they are at least as effective as warfarin for stroke prevention in patients with AF or for the treatment of VTE but are associated with a significant reduced risk of intracranial bleeding and are more convenient to administer.[23] However, because the most common ADR in all currently approved anticoagulants is bleeding, precision pharmacotherapy can help hematologists to cost-effectively guide oral anticoagulant therapy to avoid this ADR with both the availability of already identified reliable genomic markers and with the choice of different approved drugs. Efforts are underway to identify genomic markers for ADRs and efficacy of the novel, now widely used direct oral FXa inhibitors and to further expand the therapeutic armamentarium (e.g., develop drugs that do not target components of the common pathway—FXa and thrombin).

DRUG TRANSPORTERS

Although passive diffusion is thought to account for tissue distribution of some drugs and their metabolites, there is a growing body of evidence that membrane transporters play an important role in drug disposition and effects. Membrane transporters are highly expressed in epithelial cells and move drugs and other xenobiotics across the gastrointestinal (GI) tract into systemic circulation and across hepatic and renal tissue into the bile and urine, respectively, for excretion. They also distribute drugs into and out of "therapeutic sanctuaries" such as the brain and testes and transport them into and out of sites of action, such as leukemia cells.

The two multispecific drug transporter superfamilies encompass the ABC and the SLC transporters.[24] SLC transporters largely, but not exclusively, mediate cellular uptake, whereas the ABC drug transporters mainly efflux substrates from cells. The function, substrate specificity, and organ distribution among different transporters vary, and comprehensive drug transporter databases are available elsewhere (see Table 8.1). There is a growing body of data on the endogenous functions (e.g., transport of metabolites, antioxidants, signaling molecules, and hormones) of ATP and SLC transporters, and a number of hematologic diseases were identified to be caused by damaging variants in these transporters (e.g., variants in *SLC19A2* in thiamine-responsive megaloblastic anemia, variants in *SLC11A2* in sideroblastic anemia, variants in *SLC4A1* in hereditary spherocytosis type 4 and southeast Asian ovalocytosis, variants in *ABCG5* and *ABCG8* in mitochondriopathies with large platelets and ovalocytes, and variants in *ABCD4* in inborn error of vitamin B_{12} metabolism). Variants in membrane transporter genes were also identified as major determinants of variation in drug disposition, response, and toxicity. For example, pharmacologically "highly important polymorphisms" were discovered and validated in the genes *ABCG2* (variant rs2231142), *SLCO1B1* (variant rs4149056), and *SLC22A1* (variants rs12208357, rs55918055, rs34130495, rs202220802, rs34059508) (International Transporter Consortium, see Table 8.1).[25] Herein we provide one selected example on how variants in *SLCO1B1* have been identified to influence the disposition and toxicity of the antileukemic drug MTX.

SLCO1B1 and Methotrexate

The SLC organic anion-transporter family member 1B1 (*SLCO1B1*) gene, for example, encodes an organic anion transporter 1B1 (OATP1B1) that is located primarily on the sinusoidal face of human hepatocytes. OATP1B1 mediates the hepatic uptake of many endogenous compounds (e.g., bilirubin) and xenobiotics such as 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (e.g., simvastatin) from sinusoidal blood, resulting in their net excretion from blood, likely via biliary excretion. A common sequence variant in the coding region of *SLCO1B1* (rs4149056) decreases the transport activity of the encoded protein and results in markedly increased plasma concentrations of drugs that are eliminated from the blood via hepatic uptake. Using GWAS, correlations have been established between variants in *SLCO1B1* and myopathy after treatment with the HMG-CoA reductase inhibitor simvastin.[2]

In the field of hematology, a GWAS identified the rs4149056 and other variants in *SLCO1B1* to be significantly associated with MTX clearance; this association was robustly confirmed with five different MTX treatment regimens in more than 1000 pediatric ALL patients.[26] MTX is mainly excreted in the kidney, and *SLCO1B1* is expressed in the liver and associated with hepatobiliary excretion, which is a relatively minor path for MTX elimination (less than 30%). However, results of targeted urinary metabolome analyses suggest that dysfunction of OATP1B1 in the liver may affect the excretion profile of endogenous and exogenous substrates through metabolite-mediated interactions, thereby influencing other transport systems in distant organs (e.g., MTX excretion in the kidney).[27] Clearly, further investigations are necessary to better characterize such a comprehensive concept of complex interactions between transporters and their substrates.

GENETIC VARIATIONS INFLUENCING DRUG TARGETS

To exert their pharmacologic effects, most drugs interact with specific target proteins, such as receptors, enzymes, or proteins involved in signal transduction, cell cycle control, or other cellular events. A comprehensive, regularly updated list of drug targets and their ligands is provided at the website of the International Union of Basic and Clinical Pharmacology (IUPHAR)/British Pharmacological Society (BPS) Guide to Pharmacology (see Table 8.1). Molecular studies have revealed that many of the genes encoding these drug targets exhibit genetic variations, which can alter the sensitivity of these targets to specific medications (e.g., *VKORC1* and warfarin effects).

The following section illustrates this, focusing on somatic genetic variants in chronic myeloid leukemia (CML) cells that alter the targets of tyrosine kinase inhibitors (TKIs).

BCR-ABL1 and Tyrosine Kinase Inhibitors in Chronic Myeloid Leukemia

Somatic genome variants caused by major structural variants, such as the t(9;22) chromosomal translocation producing the *BCR-ABL1* fusion gene, are major mechanisms underlying many forms of hematopoietic malignancies. The increased tyrosine kinase activity of the BCR-ABL1 protein (encoded by the chimeric BCR-ABL1 or "Philadelphia [Ph] chromosome") is the driving oncogenic event in the majority of patients with CML and in a subset of patients with poor-prognosis ALL. This realization resulted in the development of specific TKIs. The treatment of CML was revolutionized with the introduction of the first TKI STI-571 (imatinib), a small-molecular-weight drug that binds to the kinase domain of ABL1, thereby leading to inhibition of tyrosine phosphorylation of proteins involved in downstream signal transduction. In the landmark phase III International Randomized Study of Interferon alpha (IFN-α) and STI-571 (IRIS) trial, imatinib monotherapy was established as the standard-of-care for CML patients, which led to a paradigm shift in cancer treatment (i.e., a more targeted therapy instead of the nonspecific inhibition of rapidly dividing cells).

Although long-term outcome of IRIS participants was excellent in the imatinib arm (with 83.3% survival at 10 years and infrequent serious side effects), up to 17% of patients had been identified to have developed resistance to imatinab within 5 years of therapy. Both, BCR-ABL1 kinase–dependent (i.e., mutations in or near to the imatinib binding site of the target kinase domain of ABL1, found in 60% of the patients who relapsed after achieving an initial response) and BCR-ABL1–independent drug resistance mechanisms were subsequently identified. The latter include reactivation of downstream signaling pathways (e.g., Janus kinase/signal transducer and activator of transcription proteins [JAK/STAT], mitogen-activated protein kinase [MAPK], or phosphatidylinositol 3-kinase [PI3K]) despite effective BCR-ABL1 inhibition; mutations in epigenetic regulators such as DNA methyltransferase 3 alpha (DNMT3A) and isocitrate dehydrogenase 1 (IDH1); or microenvironmental factors such as cytokines that influence, for example, STAT3 phosphorylation independent of BCR-ABL1 kinase activity. BCR-ABL1 kinase–independent resistance mechanisms predominate in primary resistant CML clones.[28] Sequence variants governing BCR-ABL1 kinase–dependent drug resistance are localized either around the phosphate binding loop (e.g., variants M244V, G250E, Q252H, Y253F, E255V), the SH2 contact and C-lobe (e.g., variants M351T, F359V), the activation loop (e.g., variant H396P, H396R), or the gatekeeper residue (variants T315I and F317L) of the imatinib binding site.[28] The identification of these variants led to the design of second- and third-generation ABL1 TKIs. Of these, currently four are FDA approved for the therapy of CML, namely nilotinib (binding to the same pocket as imatinib but with higher affinity; strong resistance: T315I), dasatinib (binds to the ATP-binding site with stronger activity against the ABL1 kinase compared with imatinib and dasatinib; strong resistance: T315I), bosutinib (similar binding site as dasatinib but lower potency; strong resistance: T315I, V299L), and ponatinib (high-affinity binding to ABL1 and efficacy also against T315I; compound mutations affecting E255V and T315I do result in drug resistance)[28] (see also the website Clinical Interpretation of Variants in Cancer [CIViC]). The relatively common T315I or "gatekeeper" variant confers resistance to imatinib, nilotinib, dasatinib, and bosutinib; therefore the third-generation TKI ponatinib was designed. Ponatinib was successfully tested in clinical trials, and its use was first approved by the FDA in 2012 for patients with CML resistant to other TKIs. However, ponatinib was temporarily suspended in 2013 due to serious vascular adverse events (VAEs; i.e., arterial and venous thromboembolic events, arterial hypertension), and VAEs are now recognized as also limiting the use of second-generation TKIs. Moreover, the strong selective pressure of ponatinib has led to the emergence of TKI resistance due to so-called compound mutations in ABL1. Compound mutations are multiple-point variants occurring in the same *BCR-ABL1* allele, and this drug-resistance mechanism is different to the emergence of multiple clones with different mutations. Computed modeling and in vitro proliferation studies were used to analyze the impact of compound mutations in *BCR-ABL1* on TKI resistance and showed, for instance, that the compound mutation Y253H/E255V induced a shift in the P-loop of the ABL1 kinase, obstructing the ponatinib binding site, resulting in resistance to ponatinib.[29] Moreover, it was found that additional acquisition of an E255V variant in T315I-positive CML confers also resistance to ponatinib.

To avoid off-target toxicities of ponatenib and to retain the ability to target the T315I variant, the allosteric inhibitor asciminib (ABL001), which binds to the myristoylation pocket of *BCR-ABL1*, was designed. Asciminib showed promising results in a phase I clinical trial in heavily pretreated CML patients (NCT02081378); that its, a major molecular response (MMR; which is a *BCR-ABL1* PCR level of 0.01% on the Internationale Scale [IS]) was achieved in 48% of patients at 12 months of therapy.[28] However, like for ATP-binding site TKIs, mutations at the binding site of asciminib can also cause resistance to this drug, and a combination of asciminib with an ATP-binding site TKI may overcome the emergence of resistant CML clones because these drugs bind at different sites of *BCR-ABL1* and have therefore different drug resistance mechanisms.

As second- and third-generation TKIs have a risk for VAEs, especially in older patients with preexisting vascular disease, TKI selection based on cardiovascular risk factors and mutational *BCR-ABL1* status is of utmost importance to guide CML therapy. Upfront and repeated monitoring of the mutational status of patients with BCR-ABL1–positive leukemias can help to select appropriate TKIs and tailor TKI treatment. Recent treatment trials also focus on combining TKIs with other drugs such as IFN-α (which can augment immune reaction against TKI-resistant residual CML clones; NCT01933906, NCT02001818) or with drugs that target signaling pathways downstream of the BCR-ABL1 kinase (e.g., the JAK inhibitor ruxolitinib; NCT01702064, NCT03610971) to overcome ABL1 kinase domain mutation–independent resistance mechanisms in order to promote deep molecular responses and to allow discontinuation of TKI therapy.[28]

ADVERSE DRUG EFFECTS PRESENTING AS HEMATOLOGIC DISORDERS

ADRs constitute a major clinical problem, and strong evidence indicates that ADRs account for approximately 5% of all hospital admissions. Moreover, two large surveys in the United States in 1998 and 2010 suggested that ADRs occurring in hospitals were the fourth to sixth leading cause of in-hospital mortality.[2] Although the factors that determine susceptibility to ADRs are unclear in most cases, there is increasing interest in the role of genetic predisposition to these ADRs; the possibility of a genetic test to identify patients at risk for rare but serious adverse effects would be of great clinical value.[30] Based on the clinical relevance of ADRs, the FDA has provided advice on the use of certain pharmacogenomic diagnostics (e.g., variants in *TPMT*, *NUTD15*, *DPYD*, *UGT1A1*, *CYP2C9*, *CYP2C19*) to avoid serious adverse drug effects; a full list of these genetic test is available on the FDA website, although contents of this site have not all been subjected to rigorous evidence-based assessment comparable with the CPIC (see Table 8.1).

CPIC recommendations on medications whose adverse effects have been associated with variability in candidate genes and manifest predominantly as hematologic abnormalities are listed in Table 8.2. In the following section, we provide information on genetic variants in G6PD that can cause acute hemolytic anemia (AHA) after administration of certain drugs.

Glucose-6-Phosphate Dehydrogenase Deficiency and Rasburicase

Occurrence of AHA after mass administration of the antimalaria drug primaquine (PQ) was first documented in some US soldiers in Korea. The so-called PQ sensitivity syndrome was more common among African Americans and clinically identical to "favism" (i.e., AHA after ingestion of fava beans). The underlying biochemical (Fig. 8.2) and genetic (variants in *G6PD*) causes of the clinical phenotype (i.e., AHA after PQ and fava beans, as well as for neonatal jaundice) were identified, and the disease was named G6PD deficiency.[31] The severity of AHA in individuals with G6PD deficiency after treatment with drugs that induce oxidative stress is also influenced by host and environmental factors (see Fig. 8.2).

The *G6PD* gene is localized on Xq28, and currently more than 160 pathogenic variants have been identified. The biochemical characterization of these variants has revealed a range of effects, such as changes in kinetic activity, thermostability, and protein folding.[32] The clinical phenotypes of G6PD variants are largely determined by a trade-off between protein stability and catalytic activity.

G6PD is an "essential gene" (i.e., complete loss of G6PD is lethal). Very rare, more complex variants, for instance, in-frame deletions in exon 10, which affect important regions within the enzyme such as the substrate binding site, can cause severe transfusion-dependent chronic nonspherocytic hemolytic anemia (CNSHA). Variants have been divided into five classes based on enzyme activity in red blood cells (RBCs) and clinical presentation: class I (CNSHA, activity less than 10%), class II (no CNSHA, activity less than 10%), class III (no CNSHA, greater than 10% to 60%), class IV (normal activity; variants G6PD B and G6PD A), and class V (higher activity). It is estimated that approximately 5% of the world's population has G6PD deficiency, and almost all of these individuals have class II or III variants.[33]

Drugs that have the potential to cause oxidative stress in erythrocytes, which results in AHA in G6PD-deficient patients, have been recently classified into two groups: (1) predictable hemolysis (i.e., AHA can be expected in a G6PD-deficient patient after administration of the drug) and (2) possible hemolysis (i.e., AHA may or may not occur, related to dosage and administration of the drug, comorbidities).[31] Drugs with predictable hemolysis include, for instance, the antimalaria drug PQ and the recombinant urate oxidase rasburicase. A comprehensive list of drugs is provided elsewhere,[31, 33] and we focus on rasburicase herein.

Rasburicase is used in the prophylaxis and treatment of hyperuricemia, and the most important indications are tumor lysis (e.g., in patients with hyperleukocytosis leukemia or lymphoma) or after acute renal failure in infants. Rasburicase catalyzes the cleavage of uric acid, thereby producing hydrogen peroxide. Normally, hydrogen

Figure 8.2 FACTORS INFLUENCING THE PHENOTYPE HEMOLYSIS IN INDIVIDUALS WITH G6PD DEFICIENCY. Damaging variants in the *G6PD* gene lead to G6PD deficiency in red blood cells, which, under oxidative stress, (1) leads to depletion of glutathione (with low cellular NADPH and GSH pools causing low activity of GPX [the enzyme that detoxifies H_2O_2]) and subsequent loss of protection against oxidation of proteins, with precipitation of denaturized hemoglobin leading to AHA, and (2) oxidation of hemoglobin (Hb) iron with formation of methemoglobin (MetHb is converted back to Hb via an NADPH-dependent reaction; as the cellular NADPH pool is low, MetHb accumulates), resulting in methemoglobinemia. The severity of AHA and tissue hypoxia in individuals with G6PD deficiency after treatment with drugs that induce oxidative stress is influenced by (3) host factors such as genetic variants in *G6PD* and comorbidities such as malaria, methemoglobinemia, and ALL, as well as environmental factors (i.e., drugs, their dose, and schedule of administration). *6PG*, 6-Phosphogluconolactone; *AHA*, acute hemolytic anemia; *ALL*, acute lymphoblastic leukemia; *G6P*, glucose 6-phosphate; *G6PD*, glucose-6-phosphate dehydrogenase; *GPX*, glutathione peroxidase; *GSH*, glutathione; *GSR*, glutathione reductase; *GSSG*, glutathione disulfide; H_2O_2, hydrogen peroxide; *NADP(H)*, nicotinamide adenine dinucleotide phosphate; *ROS*, reactive oxygen species.

peroxide is promptly inactivated via glutathione peroxidase (GPX). However, in individuals with G6PD deficiency, the activity of GPX is markedly reduced due to impaired glutathione metabolism, and rasburicase induces AHA and often significant methemoglobinemia. This can cause severe tissue hypoxia, especially in patients with leukemia who have already reduced RBC counts, and fatalities have been reported after rasburicase administration in ALL patients with G6PD deficiency (see Fig. 8.2).[33]

The FDA and the European Medicines Agency (EMA) have contraindicated the use of rasburicase in individuals with G6PD deficiency. However, tumor lysis syndrome (TLS) is also a life-threatening condition, and one must carefully balance the risk of reversible severe AHA and methemoglobinemia, which can be treated via RBC transfusions, and the risk of renal failure and hyperkalemia in TLS. Online enzyme activity testing before the use of rasburicase (i.e., providing results within 1 hour) is an ideal but not commonly achievable scenario. More information on available genetic and activity test options is provided in the updated CPIC guidelines (see Table 8.2).[33]

Of interest are the results of a recent pharmacoepigenetic investigation in which HDACis selectively reinstated enzyme activity in G6PD-deficient erythroid precursors in vitro by boosting *G6PD* gene transcription.[34] Whether administration of the epidrug HDACi sodium butyrate can also increase G6PD activity in patients with G6PD deficiency to levels that protect their erythrocytes from oxidative damage by rasburicase or other oxidative stressors and if such an approach is not associated with severe side effects remain to be proven. However, the ability of HDACi to increase the transcription of a subset of active genes, such as *G6PD*, would offer a novel and appealing therapeutic approach, especially for the subset of patients with severe forms of enzymopathies, such as CNSAH class I or II G6PD deficiency.

A different PGx approach to establish drug therapy for patients with severe G6PD deficiency was recently reported. Using crystallographic studies and mutagenesis analyses, researchers identified the structural and functional defects of one common variant in *G6PD* (i.e., "Canton variant [R459L], which is the most common causative variant in patients with G6PD deficiency in China and Southeast Asia). The Canton variant is associated with severe G6PD deficiency (class II, 18% activity). Using high-throughput screening, a small molecule—AG1—was identified, which increases the activity of wild-type G6PD, the Canton variant, and several other common G6PD variants in vitro. Clearly, further studies are necessary to investigate if treatment with AG1 can result in clinical benefit for a subset of patients with severe forms of G6PD deficiency.[32]

DRUG DEVELOPMENT

Optimizing the selection and dosage of medications is a principal goal of PGx. Another important application is in drug development, which is evolving in parallel with improved insights into the pathobiology of diseases (i.e., target identification) and into the mechanisms by which medications exert their pharmacologic effects as well as mechanisms of drug resistance. Improved insights into the mechanism(s) of diseases and drug actions in target cells can help to identify novel therapeutic targets (e.g., targetable key molecules in signaling pathways that are dysregulated in a certain disease) or to elucidate mechanisms that confer drug resistance (e.g., inactivation of TPs via NT5C2 or PRPS1), and this knowledge can be used to engineer drugs that induce or amplify treatment effects or bypass resistance mechanisms, or both.

Here we focus on examples to show how recent novel insights from ALL biology coupled with PGx investigations have helped to develop strategies to further improve outcome in so-called high-risk subgroups in young patients with B-cell ALL (HR B-cell ALL) who still have poor outcomes (i.e., less than 70% overall survival [OS] estimates) despite intensive contemporary therapies.

Drug Development in Pediatric High-Risk B-Cell Acute Lymphoblastic Leukemia

Currently more than 20 subtypes of B-cell ALL have been defined by constellation of genomic alterations, and these subtypes can also be grouped according to outcomes achieved with current therapies.[35] Children with the “low-risk” B-cell ALL subtypes ETV6-RUNX1 (occurring in 20% to 25% of patients) and high hyperdiploid ALL (51 to 67 chromosomes; 20% to 30% of patients) have excellent outcomes, with greater than 90% OS estimates. “Intermediate-risk” B-cell ALL subtypes include ETV6-RUNX1–like (3%), TCF3-PBX1 (5%), DUX4-ERG (5%), PAX5alt and PAX5 P80R (4% to 5%), ZNF384-r, and iAMP21 (2.5%) ALL; patients with this subtypes have OS estimates of 70% to 90% in more developed countries with current personalized therapies.[36] Despite the high prevalence of this prognostic favorable B-cell ALL subtypes in children in high-income countries, ALL remains a leading cause of death from disease in children older than 1 year, and treatment of children with HR-ALL (approximately 30% of patients) remains one of the greatest challenges in pediatric oncology. HR-ALL features include the resistance of leukemia cells to steroids and multidrug therapy (clearance of leukemia blasts in the peripheral blood, bone marrow, and sanctuary sites), and the presence of certain genetic alterations in leukemia cells—for instance, lysine methyltransferase 2 A gene rearrangements (KMT2A-r ALL, formerly MLL-r ALL; 5% of patients), the BCR-ABL1 fusion gene (BCR-ABL1 ALL; 3%), hypodiploidy (less than 44 chromosomes; 2.5%), myocyte enhancer factor 2D rearrangements (MEF2D-r ALL; 2.5%), and the “BCR-ABL1–like ALL” (14%).[36]

The introduction of TKIs in the treatment of BCR-ABL1 ALL has led to a significant improvement in outcome in this HR B-cell ALL subtype, as demonstrated by results from the Children’s Oncology Group (COG) AALL0031 trial. The following sections provide examples on the development of novel approaches to treat infants, children, as well as adolescents and young adults (AYAs), with other HR B-cell ALL subtypes.

Identification of Novel Therapies for KMT2A-Rearranged Infant ALL

Infants (age less than 1 year) with ALL (nearly all have B-cell ALL, with only 5% T-cell ALL) have long been recognized to have very poor outcomes when treated with ALL standard therapy. The identification that transcriptome profiles separate infant ALL from ALL and AML and that infant ALL blast cells are highly sensitive to cytarabine in vitro (similar to AML) provided the rationale to establish an ALL/AML hybrid treatment concept.[37] Indeed, Interfant-99 hybrid therapy (NCT00015873) resulted in better but still poor outcomes (5-year event-free survival [EFS] for infants with KMT2A-r ALL remains less than 40%), and further improvements of infant ALL therapy are needed. Of note, the pharmacokinetics of many conventional antileukemia drugs differ between infants and older children, and an intensive induction therapy concept (with intensive dosing of standard ALL medications) in the COG AALL0631 trial had to be modified because of a high rate of fatal toxicities during this treatment phase. Therefore the unique drug metabolism profile in infants (i.e., developmental pharmacology) needs to be considered when planning future infant ALL trials, and novel, less toxic therapies are needed.

Approximately 80% of infants with ALL have rearrangements of the *KMT2A* gene (KMT2A-r) at 11q23 and KMT2A translocations. Next-generation sequencing approaches identified that infant KMT2A-r ALL has one of the lowest frequencies of somatic mutations of any as-yet sequenced cancer, with a mean of 1.3 nonsilent mutations.[38] Wild-type *KMT2A* encodes a histone methyltransferase that targets lysine 4 on histone 3 (H3K4), and leukemias carrying KMT2A-r can be considered as prototypical cancers driven by dysregulated epigenetic mechanisms. *KMT2A* rearrangements lead to the loss of the catalytic methyltransferase domain, with subsequent in-frame fusion to one of greater than 100 known translocation partners. The prognostic significance of *KMT2A* rearrangement varies according to the fusion partner and the disease; for example, 50% of infants with AML have a KMT2A-r, but this is not associated with a poorer prognosis. Interestingly, KMTA2-r ALLs in older children have more somatic mutations, with a mean of 6.5 per patient versus 1.3 mutations in infants. In infant ALL the most common partner gene (49% of patients) is *AFF1*, which encodes AF4/FMR2 family member 1 (formerly *AF4*) on chromosome 4. The resulting chimeric oncoproteins interact with another methyltransferase—DOT1-like histone H3K79 methyltransferase (DOT1L)—which then methylates lysin 79 in the globular region of histone H3 (H3K79) at KMT2A target genes, causing aberrant gene expression and leukemogenesis. Inhibition of DOT1L has emerged as an attractive concept for therapeutic intervention in KMT2A-r leukemias, and in vitro and animal studies have shown that the small molecular inhibitors of DOT1L selectively target KMT2A-r leukemia cells.[39] In a phase I trial for adults with KMT2A-r leukemias (NCT01684150) monotherapy with the epidrug pinometostat (EPZ-5676) demonstrated evidence of DOT1L target inhibition but limited clinical responses (only 2 of 51 had complete responses). In a pediatric phase I trial (NCT02141828), transient decreases in peripheral or marrow leukemic blasts were reported in 7 of 18 children with relapsed/refractory KMT2A-r leukemia treated with pinometostat, but these reductions did not meet formal thresholds for objective response. However, the observed safety profile of pinometostat provides potential for exploration of a combination with standard chemotherapy, and a phase Ib/II trial (NCT03724084) in adults with KMT2A-r AML is currently enrolling patients; if this approach proves to be successful, it remains primed for testing in infants with KMT2A-r ALL. Because KMT2A-r infant ALL can be considered as an epigenetic disease, other epidrugs are being incorporated into clinical trials based on preclinical efficacy data; for example, the demethylating agent azacitidine is currently being investigated in combination with the Interfant chemotherapy backbone (NCT02828358).[37]

A different approach focuses on targeting the class III receptor tyrosine kinase (RTK) Fms-related receptor tyrosine kinase 3 (FLT3). Using genome-wide gene expression analyses, the *FLT3* wild-type gene was identified as being overexpressed in KMT2A-r ALL. FLT3 inhibitors have been shown to inhibit growth in cells that overexpress FLT3.[40] The COG AALL0631 trial investigated the combination of the FLT3 inhibitor lestaurtinib given after induction therapy in combination with an intensive chemotherapy backbone in children with KMT2A-r ALL. However, the trial failed to demonstrate a benefit from the addition of lestaurtinib.

In addition, novel CD19-directed immunotherapies, such as the treatment with the bispecific antibody blinatumomab or with CAR T cells, are being explored in infant KMT2A-r ALL. For example, a pilot trial of blinatumumab in combination with the Interfant chemotherapy backbone has been initiated (trialregister.nl NTR6359). However, potential limitations of such approaches are that the CD19 antigen is not uniformly expressed in KMT2A-r leukemias and that "class switching" from lymphoid to myeloid phenotypes has been reported in infants with KMT2A-r ALL during CD19-targeted immunotherapies. Moreover, manufacturing CAR-T cells from autologous infant T cells is challenging. To overcome this problem, novel gene-editing techniques were developed to simultaneously introduce the CD19 CAR construct and disrupt mediators of allogeneic rejection via transcription activator–like effector nuclease (TALEN)-mediated gene editing of T-cell receptor α chain and CD52 gene loci in healthy donor T cells, creating allogeneic universal CAR-T (UCART19) products.[37] Of note, two infants with relapsed KMT2A-r ALL were treated and achieved molecular remissions via such UCART19 cells, and these cells persisted until conditioning ahead of successful subsequent allogeneic stem cell transplantation.

Although infants with KMT2A-r ALL still fare worse than older children with ALL, the aforementioned approaches hold promise to improve outcomes in these patients via novel personalized therapies that will be tested in international cooperative treatment trials.

Identification of Novel Therapies for "BCR-ABL1–Like" ALL

In contrast to the low- and intermediate-risk B-cell ALL subtypes (which account for approximately 70% of childhood ALL cases), B-cell ALL with the *BCR-ABL1* fusion gene responds poorly to conventional ALL therapy, and patients with BCR-ABL1 ALL belong to the HR group, with less than 70% OS estimates. BCR-ABL1 ALL is rare in children (1 to 15 years, 4.2%) but is more common in adolescents (16 to 20 years, 5.9%) and young adults (21 to 39 years, 22%); this is a contributor to the overall poorer prognosis of AYAs with ALL.[36]

In 2009, genome-wide transcriptome analyses identified a subtype of HR B-cell ALL that has a gene expression profile similar to that of BCR-ABL1 ALL.[41, 42] In contrast to BCR-ABL1 ALL, leukemia cells in the identified subtype did not harbor the *BCR-ABL1* fusion gene; therefore this subtype has been named BCR-ABL1–like ALL. BCR-ABL1–like ALL is more common but has the same age distribution pattern as BCR-ABL1 ALL (i.e., 1 to 15 years, 11.9%; 16 to 20 years, 20.6%; 21 to 39 years, 27.4%). Because BCR-ABL1–like ALL has an activated kinase gene expression profile resembling BCR-ABL1 ALL, it was speculated that genetic alterations that can influence tyrosine kinase signaling pathways similar to those downstream of BCR-ABL1 might be involved in the pathogenesis of BCR-ABL1–like ALL. Indeed, kinase-activating alterations (rearrangements, sequence variants, and CNVs) were subsequently identified in comprehensive analyses, which included transcriptome, WGS, and WES.[43]

Subsequent large-scale investigations corroborated and extended early findings in BCR-ABL1–like ALL and identified this subtype to be a heterogeneous disease with a wide range of genetic alterations (i.e., more than 70 discrete alterations reported as of January 2020).[43, 44] However, two major subgroups, distinguished by the type of cytokine receptor or kinase alterations, emerged. For example, 60% of adolescents with BCR-ABL1–like ALL had rearrangements in the lymphoid signaling receptor gene *CRLF2* (encoding cytokine receptor–like factor 2) and concomitant mutations in *JAK1* or *JAK2* (which encode the JAKs). These rearrangements (e.g., the frequently observed *PAX5-JAK2* fusion), when ectopically expressed in cell lines, activated JAK-STAT signaling and conferred cytokine-independent proliferation that can be suppressed by the JAK2 inhibitor (JAKi) ruxolitinib in vitro. Preclinical studies have shown activity of JAK in vivo in CRLF2-r and other JAK pathway mutant BCR-ABL1–like ALL patient-derived xenograft models. In a phase I/II trial (NCT02420717), low-dose ruxolitinib with chemotherapy was tested for adolescents and adults with relapsed/refractory CRLF2-r/JAK-mutant ALL; this combination therapy was well tolerated, but only limited efficacy was observed. In a phase II trial (AALL1521, NCT02723994), the COG is testing the safety and efficacy of ruxolitinib addition to chemotherapy in children and AYAs with newly diagnosed BCR-ABL1–like ALL and CRLF2 rearrangements or other JAK pathway alterations.[44]

The second major subgroup within the BCR-ABL1–like ALL cohort was identified to have so-called ABL class-alterations (ABL class-mutant ALL), namely, fusions that involve the Abelson-related (ABL)-class kinase genes (e.g., *ABL1* and *ABL2*), platelet-derived growth factors A and B (*PDGFRA*, *PDGFRB*), or colony-stimulating factor 1 receptor (*CSF1R*). The use of ABL TKIs, such as imatinib and dasatinib, has markedly improved survival for patients with BCR-ABL1 B-cell ALL, and it can be anticipated that patients with BCR-ABL1–like B-cell ALL might also benefit from such a therapy. Indeed, preclinical studies have shown promising results in treating ABL class-mutant Ph-like ALL with imatinib or dasatinib; in addition, anecdotal case reports have shown impressive activity in refractory patients with the combination of imatinib or dasatinib with chemotherapy, especially for PDGFRB-r (e.g., *EBF1-PDGFRB*) BCR-ABL1–like ALL. The combination of dasatinib with chemotherapy is tested in patients with newly diagnosed ABL class-mutant BCR-ABL1–like ALL in ongoing trials of the COG (AALL1131, NCT01406756) and the SJCRH Total XVII (NCT03117751).[44]

Other less frequently observed targetable alterations affect the *NTRK3* gene, which encodes the neurotrophic tyrosine kinase receptor type 3 and *ETV6* (ets variant 6). Malignancies with *NTRK3* fusions (e.g., infantile fibrosarcomas) have been shown to respond well to TRK inhibitors such as crizotinib and larotrectinib; larotrectinib had clinical activity in an adult patient with ETV6-NTRK3-r BCR-ABL1–like ALL.[45]

In summary, this provides evidence that kinase-activating genetic alterations are biologically relevant drivers in BCR-ABL1–like ALL and that the genetic signature can help to guide the use of additional drugs such as TKIs, JAK2, or TRK inhibitors. However, rapid molecular profiling is needed to identify potentially actionable mutations in patients with BCR-ABL1–like ALL, and additional prospective trials are needed to establish their benefit in the clinical setting. In contrast to children, outcomes in ALL have not improved significantly during recent decades in the AYA cohort; because BCR-ABL1–like ALL is the most common subtype in AYAs, the introduction of signaling pathway inhibitors may be an attractive strategy to improve outcome in these patients who have been therapeutically neglected for too long.

FUTURE DIRECTIONS

PGx was perhaps the earliest application of precision medicine and has already been proven to be an important approach to personalize drug therapy, especially in situations where common variants in key pharmacogenes, encoding essential proteins for drug transport, metabolism, or targets, have large effects on drug disposition and/or action. Examples are variants in *TPMT* and *NUDT15* and their influence on TP toxicity and activity, variants in *G6PD* and their influence on rasburicase toxicity, variants in *VKORC1* and *CYP2C9* and their effects on warfarin pharmacology, damaging variants in cytochrome P450, family 2, subfamily C, and polypeptide 19 *(CYP2C19)* and their influence on clopidogrel (antiplatelet medication) activation resulting in reduced drug effect and increased risk of major adverse cardiovascular events, or variants in dihydropyrimidine dehydrogenase *(DPYD)* and toxicity of fluoropyrimidine-based anticancer therapy with capecitabine or fluorouracil. However, even in the case of the aforementioned examples, there is a relatively slow pace of translating PGx knowledge into clinical practice. Laboratory tests (e.g., liver and kidney function tests) are widely used to adjust drug dosages. Although technology for testing relevant PGx biomarkers is widely available, simple, robust, and inexpensive, genotyping tests are yet rarely used to optimize drug therapy. Because genotyping at the time of prescribing is compromised by the relatively long delay until genotype results are available, preemptive genotyping early in a person's life or at the time of initial illness is a more efficient and cost-effective approach. In addition, because a person's germline genotype does not change over a lifetime, it needs to be done only once. Recently, preemptive panel-based strategies were implemented, including the so-called PGx-Passport, which contains a set of 58 germline-variant alleles located within 14 genes considered to be pharmacogenomically actionable according to the Dutch Pharmacogenetics Working Group (DPWG),[46] and a panel testing within the PREemptive PGx Testing for Preventing Adverse Drug Reactions (PREPARE; NCT03093818) trial from the European Union (EU) Ubiquitous-PGx (U-PGx) Study group. The future likely holds that WGS or WES data will be the most comprehensive and cost-effective approach for diagnosing patients with inherited or acquired (somatic) genome variants that can guide the selection and dosing of a growing number of medications.

To implement a change in clinical practice, mainly RCTs are currently used to prove an approach to be superior to standard practice. The number of completed RCTs studying PGx-informed preemptive dosing compared with conventional dosing is rather low, and it is not clear that RCTs are essential (RCTs have not been done to show superiority of many treatments, nor the benefits of parachutes for those jumping from airplanes).[47, 48] However, most reported results from such RCTs are in favor for the PGx-guided drug dosing regimens (e.g., *CYP2C9*, *VKORC* and warfarin dosing, NCT01119300; NCT01006733; *DPYD* and fluoropyrimidine toxicity, NCT02324452; *TPMT* and TP toxicity, NCT00521950). Currently recruiting prospective trials include the PREPARE (NCT03093818) trial from the EU U-PGx Study group, the Tailored Antiplatelet Initiation to Lessen Outcomes due to Decreased Clopidogrel Response After Percutaneous Coronary Intervention (TAILOR-PCI; NCT01742117), and the Patient Outcome After Primary PCI (POPular; NCT01761786) trial. These RTCs will further inform the field of precision medicine on the utility of PGx-based drug dosing.

Another instrument for clinical implementation of PGx are PGx drug labels in the Summary of Product Characteristics (SmPC), and in 2019 approximately 15% of prescribed drugs were reported to carry PGx information in their SMPCs in the United States. PGx guidelines and SmPC labels for the use of genomic biomarkers in clinical practice are provided, for example, by the CPIC, FDA, DPWG, and EMA. However, the consensus of actionable PGx labels of 184 different gene–drug interactions between the FDA and EMA was only 54%; further efforts are necessary to harmonize the PGx drug labels in the SmPCs.[49]

Sophisticated electronic health record (EHR) systems, in combination with clinical decision support systems (CDSSs) that include PGx information as one variable, create a solid basis for implementation of PGx and other diagnostics; initiatives such as the "Clinical Implementation of PGx—PG4KDS protocol" at St. Jude Children's Research Hospital provide proof-of-principle on the feasibility to use genetic information to prescribe medications as a routine part of clinical care.[50, 51]

The recent unprecedented gain of insights into the human genome and genomic variations among individuals has already changed the practice of medicine. High-throughput technologies, such as hybridization-based microarray approaches and next-generation sequencing technologies, are available for genome-wide analyses of genomic variants, gene expression patterns, epigenetic patterns, and proteomic and metabolomic profiles. Moreover, sophisticated methods have been developed to integrate these data to uncover genotype–phenotype interactions, and some of the most important methods are metadimensional and multistaged analyses. The application of these genome-wide tools has already yielded significant insights into the biology of diseases and complex drug actions and led to interesting novel PGx discoveries. For example, by moving beyond candidate gene approaches, a genetic risk score derived from 61 individual variants was identified to separate cases from controls for drug-induced QT prolongation in a recent GWAS.[2] However, the extent to which such multigene markers can explain the complex genomic architecture of diseases or drug responses remains to be further explored.

Novel genomic testing tools are also being used to elucidate differences between genomes of normal cells and cancer cells (e.g., the Pediatric Cancer Genome Project; see Table 8.1), and this knowledge has proven potential to illuminate paths toward novel prognostic markers (those that can be used for risk stratification in clinical trials) and/or novel therapeutic targets (those that can be used to discover new medications). For example, novel comprehensive genomic approaches (including RNA sequencing [RNA-seq], WES, WGS, and gene expression profiling) have helped to identify novel subtypes of B-cell leukemia (e.g., DUX4-r ALL, PAX5 P80R ALL, PAX5-altered [PAX5alt] ALL, ETV6-RUNX1–like ALL, ZNF384-r ALL, and MEF2D-r ALL) and to gain insights in how leukemia cells become resistant to TPs during antimetabolite-based maintenance therapy via darwinian selection of ALL clones which harbor variants in *PRPS1* or *NT5C2*. This knowledge from precision oncology studies can be used to stratify patients based on their recently identified novel risk profiles into different treatments or to develop strategies to overcome their drug resistance mechanisms. Many efforts are underway around the globe to identify molecularly informed therapeutic targets in precision oncology; in pediatric oncology; these trials include the US National Cancer Institute (NCI) Pediatric Molecular Analysis for Therapy Choice (MATCH; NCT03155620) trial, the Precision Oncology for Young People (PROFYLE) trial in Canada, the European Proof-of-Concept Therapeutic Stratification Trial of Molecular Anomalies in Relapsed or Refractory Tumors (ESMART; NCT02813135), and the German INdividualized Therapy FOr Relapsed Malignancies in Childhood 2 (INFORM2; NCT03838042) trial.

One important consideration in modern medicine is that clinically useful approaches must also be cost effective. It was recently reported that the costs of developing new molecular entities (NMEs) into approved drugs continue to increase and range from US$3 billion to $10 billion per launched NME. However, only 5% to 10% of candidate NMEs in early clinical stage trials will become approved drugs. Of note, there is evidence that drug targets with genetic support are twice as likely to become approved, which supports investments into PGx investigations for pharmaceutical companies being beneficial.[52] In addition, the cost for the first full human genome sequence was approximately US$3 billion; this cost is now (as of 2019) approximately US$1000. The markedly lower cost for robust genotyping points to an exciting future for genomics and PGx research and translation, suggesting that the current approach to selecting medications (often "trial and error") will continue to evolve into more scientific-based methods for selecting the optimal medications and doses for individual patients—with genomics playing an increasing role in such therapeutic decisions (Fig. 8.3). As PGx research expands the number of robust associations between genome variation and drug response, the challenges of successful clinical translation and implementation will be a hurdle that will need to be overcome for precision medicine to become a common reality.[53]

Figure 8.3 COMPLEXITY IN SELECTING OPTIMAL MEDICATIONS BASED ON COMBINATIONS OF GERMLINE AND SOMATIC GENOMIC VARIATION IN CANCER. Somatic (tumor) and germline (normal) genome variation is reflected for three hypothetical patients with Ph-like acute lymphoblastic leukemia (ALL), based on actual genome variants documented from sequencing patients with this disease. For each hypothetical patient, genes indicated have already been shown to have functional alterations in ALL (mutations or structural alterations in leukemia cells, inherited variants altering function in germline DNA), and those with mutations in each patient are indicated in bold font with an asterisk. Somatic variants are often activating, whereas germline genes are typically loss-of-function (*TPMT*, *NUDT15*, and *CYP2D6*) or more rarely gain-of function (*CYP2C19* and *CYP2D6* duplication alleles). Potential selection of medications targeting somatic mutations is based on in vitro or in vivo activity of each medication against target proteins. Multiple variants often occur in the same leukemia cell, as documented in prior sequencing studies, and often only a subset is treated, as depicted for each patient. All inherited germline variants are essentially always present in the tumor (not depicted). Selection of optimal therapy using inherited germline variants follows evidence-based Clinical Pharmacogenetics Implementation Consortium (CPIC) guidelines (for medications within the *red box*). A substantial number of additional somatic and inherited genome variants are known to exist in this disease, adding further complexity to evidenced-based selection of optimal treatment. *ABL1*, ABL proto-oncogene 1; *CRLF2*, cytokine receptor–like factor 2; *CSF1R*, colony-stimulating factor 1 receptor; *CYP2C19*, cytochrome P450 family 2 subfamily C member 19; *CYP2D6*, cytochrome P450 family 2 subfamily D member 6; *EPOR*, erythropoietin receptor; *FAK-I*, focal adhesion kinase inhibitor; *FLT3*, Fms-related receptor tyrosine kinase 3; *FLT3-I*, Fms-related receptor tyrosine kinase 3 inhibitor; *G6PD*, glucose 6-phosphate dehydrogenase; *IL7R*, interleukin-7 receptor; *IL7Rpath-I*, interleukin-7 pathway inhibitor; *JAK 1–3*, Janus kinase 1–3; *JAK-I*, Janus kinase inhibitor; *NTRK3*, neurotrophic receptor tyrosine kinase 3; *NUDT15*, nudix hydrolase 15; *6MP*, 6-mercaptopurine; *RAS*, Ras proto-oncogene, GTPase; *SH2B3*, SH2B adaptor protein 3; *TPMT*, thiopurine S-methyltransferase; *TSLP*, thymic stromal lymphopoietin; *TYK2*, tyrosine kinase 2; *TYK2-I*, tyrosine kinase 2 inhibitor. *(Courtesy Evans WE, Pui CH, Yang JJ. PART II CELLULAR BASIS OF HEMATOLOGY

CHAPTER 9

HEMATOPOIETIC STEM CELL BIOLOGY

Marlies P. Rossmann and John P. Chute

Hematopoietic stem cells (HSCs) are characterized by their unique ability to self-renew and give rise to the entirety of the blood and immune system throughout the lifetime of an individual.[1–3] HSCs are very rare cells, representing approximately one in 100,000 bone marrow (BM) cells in the adult.[4] The concept of the existence of an HSC that is capable of reconstituting hematopoiesis in vivo was first introduced more than 70 years ago, when Jacobson et al.[5] demonstrated that lead shielding of the spleen protected mice from otherwise lethal γ-irradiation.[5] Subsequently, Jacobson and colleagues[6] reported that similar radioprotection of mice could be achieved via shielding of one femur. Shortly thereafter, it was demonstrated that intravenous injection of BM cells also provided radioprotection of lethally irradiated mice.[7] Interestingly, investigators initially hypothesized that the radioprotected spleen or BM provided soluble factors that mediated radiation protection.[8,9] However, subsequent experiments by Nowell et al.[10] and Ford et al.[11] critically demonstrated that transplanted BM cells provided radioprotection directly via cellular reconstitution of the blood system. The historical significance of these studies cannot be overestimated because they provided the basis for not only the ultimate isolation and characterization of HSCs but also for the field of hematopoietic stem cell transplantation.

Subsequent landmark studies by Till and McCulloch[12] demonstrated that transplantation of limiting doses of BM cells gave rise to myeloid and erythroid colonies in the spleens of irradiated recipient mice. Importantly, Till and McCulloch showed that the numbers of colonies detected in recipient mice was proportional to the numbers of BM cells injected into the irradiated mice, suggesting that a particular population of hematopoietic cells was capable of reconstituting hematopoiesis in vivo.[12–14] The clonogenic nature of a subset of BM cells was definitively shown when these investigators irradiated BM cells and then transplanted the cells into lethally irradiated mice. Persistent chromosomal aberrations were demonstrated in spleen colonies in recipient mice.[15] It was subsequently shown that cells within the spleen colonies were radioprotective of lethally irradiated mice and contained myeloid, erythroid, and lymphoid cells.[12,16] Taken together, these data strongly suggested the presence of hematopoietic stem or progenitor cells that were capable of in vivo engraftment and generation of multilineage progeny from a small number of parent cells.[17]

EMBRYONIC ORIGIN OF HEMATOPOIETIC STEM CELLS

Mammalian hematopoiesis occurs in several waves, which are separated temporally and spatially and produce different cell types: a transient first "primitive" is followed by a "prodefinitive" and then a "definitive" wave, which persists through life.[18–20] While most of the evidence is derived from the mouse, data from humans, albeit limited, point to a very comparable hematopoietic program.[21,22]

During embryogenesis, the hematopoietic cells of the first, primitive wave are formed when cells from the epiblast that constitute the prospective mesoderm ingress and migrate through the primitive streak between the endoderm and ectoderm, both in the embryo proper and in the extraembryonic yolk sac (YS). In the latter, mesodermal cells aggregate to form blood islands surrounded by visceral endodermal cells on mouse embryonic day (E) 7 to 7.5. The close proximity of erythroid cells and vascular endothelium in YS blood islands, their origin from mesoderm, and their simultaneous differentiation led to the proposal of a common precursor, the hemangioblast, over a century ago.[23,24] In support of this hypothesis, a spontaneous zebrafish mutant, *cloche* (named for its bell-shaped heart because of the loss of endothelium), lacks both vasculature and hematopoietic cells but no other mesodermal lineages such as cardiac progenitors.[25,26] The gene mutated in *cloche* was recently cloned and encodes a PAS (PER-ARNT-SIM) domain–containing basic helix-loop-helix (bHLH) transcription factor (*npas4l*), which belongs to the same class that also includes the aryl hydrocarbon receptor and hypoxia-induced factor (HIF)-1α.[26a] Also, mice lacking FLK1 (VEGFR2, a receptor for vascular endothelial growth factor), expressed on endothelial (progenitor) cells, fail to develop both vascular endothelium and blood islands during embryogenesis.[27,28] Indeed, gene tracing studies in mouse and human embryonic stem cell cultures have identified a progenitor with both hematopoietic and endothelial potential.[29–31]

Primitive hematopoiesis encompasses the generation of primarily large erythroid cells and primitive macrophages.[32–34] Following this initial wave, beginning at mouse E8.25, erythromyeloid progenitors (EMPs) are generated as prodefinitive progenitors.[35,36] Both waves arise transiently in the YS during a time comparable to the first trimester in humans,[37] but the cells lack the capacity for self-renewal and multilineage differentiation present in definitive HSCs. The emergence of EMPs during development is presaged by ckit+ EMP precursors that are characterized by the expression of toll-like receptor 2 (TLR2) at E7.5.[38] Three lineage-tracing studies recently demonstrated that embryonic erythropoiesis is sustained completely by YS EMPs, rather than HSC-derived progenitors.[39] Remarkably, Hoxa neg/low Kit+CD41+CD16/32+ HSC-independent EMPs from the YS have also been shown to give rise to NK cells with cytotoxic capability,[40] and YS EMPs produce osteoclast precursor cells that create space for post-natal BM hematopoiesis.[41,42] Interestingly, epidermal γδ T cells, also known as dendritic epidermal T cells, function in the adult epidermis, and are also derived from YS progenitors.[43] Utilizing single cell transcriptomic analysis and single cell cultures of YS-derived myeloid progenitors, Bian et al. recently provided a comprehensive characterization of the spatiotemporal dynamics of early macrophage development from YS progenitors during embryogenesis.[44] This study provides unprecedented insight into the distinct biology of tissue resident macrophages that are derived from YS progenitors. Importantly, Stremmel et al.[45] showed that CX3DR1+ YS-derived pre-macrophages migrate between embryonic day 8.5

through day 12.5 via the bloodstream into embryonic tissues where they take up long-term residence.

Definitive HSCs capable of long-term (LT), multilineage reconstitution of irradiated adult recipient mice appear at E10.5 in the intraembryonic region encompassing the aorta, gonads, and mesonephros (AGM), in particular in hematopoietic intra-aortic clusters in the ventral wall of the dorsal aorta.[20,46–48] Then, within a remarkably short period of 1.5 days during embryonic development, virtually all HSCs are generated that will replenish the hematopoietic system throughout fetal and adult life.[49,50] Studies by Ganuza et al.[51] utilizing cultured 2 to 7 somite pairs (sp) murine embryonic explants and 2 to 7 sp YS explants confirmed that the embryo, not the YS, is the source of definitive HSCs. Several complementary studies using lineage tracing experiments in both mice and zebrafish have demonstrated that within the dorsal aorta, hemogenic endothelial cells (ECs) are the direct precursors of definitive HSCs.[50,52–56] In a process known as endothelial-to-hematopoietic transition (EHT), HSCs bud off the hemogenic endothelium to form intra-aortic hematopoietic clusters from which they are released into circulation. Interestingly, while the AGM gives rise to HSCs, it is not the site of hematopoietic differentiation.[57] Rather, HSCs colonize the fetal liver where they expand and then differentiate (Ref. 58 and references therein).

Recent advances in single cell labeling and single cell transcriptomic analysis has allowed the isolation and characterization of a population of "pre-HSCs" during murine development.[59] CD45+ pre-HSCs in the AGM were shown to have a unique molecular signature and activation of mechanistic target of rapamycin (mTOR) was reported to be indispensable for the emergence of HSCs.[59] Separate studies which evaluated ex vivo maturation of HSCs from pre-HSCs showed that ex vivo matured HSCs and fetal liver HSCs express programmed death ligand 1 (PDL1), among other immune response genes, although PDL1 expression was not required for engraftment of embryonic HSCs.[60]

Evidence from studies in mice suggests that some definitive hematopoiesis also occurs at sites other than the AGM. By E12 the fetal liver contains more HSCs than can be accounted for by HSCs generated in the AGM alone.[61] Quantitative analysis of HSC distribution showed that both YS[61] and placenta[62,63] generate definitive HSCs that migrate to the liver and other hematopoietic sites.[64] Lastly, a c-Myb- and thus HSC-independent cell lineage that emerges between E8.5 and E9.5 in the YS has recently been shown to give rise to YS macrophages and later on to tissue macrophages in brain (microglia), liver (Kupffer cells), and skin (Langerhans cells).[65]

Human induced pluripotent stem cell models and studies of zebrafish have suggested that a population of immune precursors may originate directly from hemogenic endothelium rather than HSCs.[66,67] Utilizing a RAG1:GFP human reporter system, Motazedian et al.[67] showed that early RAG1+ cells could differentiate into CD4+CD8+ T cells, also possessed B-cell, myeloid, and erythroid potential, while also expressing endothelial markers, and resided within CD31+ endothelial structures. The authors concluded that a wave of T-cell development might originate directly from hemogenic endothelium via a RAG1+ intermediate population.[67] Utilizing a novel technique called "ScarTrace," a single cell sequencing strategy to quantify the clonal history and cell type of thousands of cells in different organs of the developing zebrafish, Alemany et al.[68] identified a novel population of immune cells in the zebrafish fin that had a distinct clonal origin from other hematopoietic cells. In keeping with these studies, Tian et al.[66] utilized temporal-spatial fate mapping analysis and time-lapse imaging to show that a wave of T lymphopoiesis could be detected in the developing zebrafish, arising from ventral endothelium in the AGM and posterior blood islands. This generation of CD4+ T cells is transient and occurs only in the early larval stage, and is later replaced by HSC-dependent T cells of all subtypes.[66] Taken together, these studies provide the impetus for further exploration of evidence for HSC-independent immune cell generation during mammalian development.[69]

DEFINITION AND CHARACTERIZATION OF HEMATOPOIETIC STEM CELLS

Phenotype

Murine Hematopoietic Stem Cells

The HSC is the most well-defined somatic, multipotent stem cell in the body. With the emergence of monoclonal antibody technology and flow cytometry[17,70,71] coupled with in vitro and in vivo functional assays,[72–77] biologists have developed reproducible methods to analyze and isolate murine and human HSCs with a high level of enrichment. In mice, Weissman and colleagues were able to show that antibody-based depletion of BM cells expressing myeloid, B-cell, T-cell, and erythroid cells along with positive selection for cells expressing c-Kit, Sca-1, and Thy-1.1^{lo} ("KTLS" cells) allowed for enrichment of HSCs to approximately one of 10 to 30 cells as measured by the capacity to provide LT, multilineage hematopoietic reconstitution in a competitively transplanted, lethally irradiated congenic mouse.[73,78–81] Because Thy-1.1 is not expressed in many strains of mice,[79] additional markers were developed, including FLK2 (FLT3), the absence of which was shown to substantially enrich for murine LT-HSCs.[82,83] Similarly, it has been demonstrated that the isolation of murine BM c-Kit$^+$Sca-1$^+$Lin$^-$ (KSL) cells based upon the lack of expression of CD34 (34$^-$KSL) enriches for HSCs with LT reconstituting capability at the level of one of 5 to 10 cells (Fig. 9.1).[84]

An alternative and effective method for isolating BM HSCs involves the use of intravital dyes, Hoechst 33342 (Ho33342) and Rhodamine 123 (Rh123).[85–89] HSCs, unlike more committed progenitor cells, efficiently efflux these dyes such that HSCs display low-intensity staining for these dyes.[89,90] Li and Johnson[88] demonstrated that HSCs capable of LT, multilineage repopulation in lethally irradiated mice were significantly enriched in the Rh123^{lo}Sca-1$^+$Lin$^-$ cells, but Rh123^{hi}Sca-1$^+$Lin$^-$ cells possessed little repopulating activity. Similarly, McAlister et al.[87] showed that isolation of Ho33342^{lo} BM mononuclear cells significantly enriched for both the potential to produce colony-forming units in the spleen (CFU-S) on day 14 and cells capable of radioprotection and multilineage reconstitution in lethally irradiated mice. A subsequent and important refinement in the use of Ho33342 to isolate HSCs was made by Goodell et al.,[89] who showed that a Ho33342 side population (SP) can be identified via the emission of Ho33342 at two wavelengths, which yields a tail profile on flow cytometric analysis. Importantly, isolation of Ho33342 SP cells has been shown to yield variable enrichment for HSCs compared with CD34$^-$FLT3$^-$KSL cells, which may be caused by the sensitivity of the assay to variations in staining techniques and batch-to-batch differences in Ho33342 dye.[91–93] However, Matsuzaki et al.[94] demonstrated that transplantation of single Ho33342 SP 34$^-$KSL cells into lethally irradiated C57BL/6 mice yielded donor cell multilineage engraftment greater than 1% in more than 95% of transplanted mice. Therefore, the combination of Ho33342 SP cells with CD34$^-$KSL markers provides a basis for isolation of highly enriched LT-HSCs from mice.[70,91–93]

A major advance in this field involved the discovery by Kiel et al.[95] that the surface expression of CD150, a member of the signaling lymphocyte activation molecule (SLAM) family, significantly enriched for murine BM HSCs. It was also shown that the absence of CD41 and CD48 on CD150$^+$ cells enriches further for the HSC population and that approximately half of CD150$^+$CD41$^-$CD48$^-$ or CD150$^+$CD48$^-$KSL cells reconstitute lethally irradiated mice competitively transplanted with limiting numbers of cells.[95] Taken together, combined isolation of SLAM- and KSL-enriched BM cells has become a reproducible and efficient strategy to isolate murine LT-HSCs with maximal enrichment (see Fig. 9.1).[96]

Expression of the gene Ctnnal1, which encodes alpha-catulin, coupled with ckit expression enriches at a very high level for murine HSCs.[97] Anatomic imaging of alpha-catulin-GFP+ckit+ cells revealed that the vast majority of these HSCs reside in the central marrow and diaphysis, in contact with leptin receptor+ and CXLC12+

Figure 9.1 PHENOTYPE OF MURINE AND HUMAN HEMATOPOIETIC STEM CELLS (HSCS). Long-term HSCs (LT-HSCs), short-term HSCs (ST-HSCs), and multipotent progenitor cells (MPPs) have precise cell surface markers that discriminate them from more committed progenitor cells. *(Adapted from Prohaska SS, Weissman I. Biology of hematopoietic stem and progenitor cells. In: Appelbaum F, Forman SJ, Negrin RS, Blume K, eds. Thomas' Hematopoietic Cell Transplantation. Chichester: Wiley-Blackwell; 2008:36–63.)*

perivascular stromal cells, and within 10 μm of sinusoidal blood vessels, not arterioles.[97] Similarly, HoxB5 expression was shown to mark HSCs with long-term repopulating capacity in mice and greater than 94% of HoxB5+ long-term HSCs were found to reside in contact with VEcadherin+ ECs, suggesting a BM vascular/perivascular niche for adult HSCs.[98] Conversely, combined analysis of three different HSC reporter lines and nine distinct niche populations in mice suggested that while HSCs were found in close association with leptin receptor+ stromal cells, sinusoidal ECs, and megakaryocytes, this distribution was not different than that of random dots.[99] The authors concluded that the distribution of HSCs in the adult BM may simply reflect the frequency of different cell types in the BM niche, rather than true enrichment in association with a particular niche cell. A more detailed description of the niches for HSCs is presented in Chapters 11 and 14.

Through a combination of single cell gene expression analysis, flow cytometric index sorting, and single cell transplantation assays, Wilson et al.[100] demonstrated that murine hematopoietic cells with high expression of endothelial protein C receptor (EPCR) combined with CD150+CD48-Sca-1^{hi} (EPCR^{hi}CD48-CD150+Sca-1^{hi} HSCs) were the most highly enriched for long-term self-renewal capacity. Additional studies by Cohen et al.[101] revealed that EPCR also regulates HSC retention in the BM via modulation of nitrous oxide production in coordination with protease activated receptor 1. Interestingly, EPCR surface expression on human cord blood (CB) HSCs has been shown to mark human cells with in vivo repopulating capacity following culture with the HSC expansion reagent, UM171.[102] Ito et al. separately demonstrated that murine CD34-HSCs displayed high expression of the angiopoietin 1 (ANGPT1) receptor gene, Tie2, and that 68% of Tie2-GFP+CD34-CD150+CD38low/-Flt3-KSL cells from Tie2 reporter mice were capable of long-term reconstitution in single cell transplantation assays.[103] Other markers recently described to enrich murine HSCs include leptin receptor, which is expressed on BM stromal cells, but has been used to isolate lepR+SLAM+HSCs which display enhanced repopulating capacity in vivo compared to lepR-SLAM+HSCs and an embryonic-like transcriptome.[104] Gulati et al.[105] reported that Hoxb5+ HSCs can be further purified using Neogenin surface expression such that Neogenin-Hoxb5+ HSCs are lineage balanced and provide long-term hematopoietic reconstitution, while Neogenin+Hoxb5+ HSCs are myeloid biased and display reduced reconstituting capacity. Finally, endothelial cell selective adhesion molecule (ESAM) is also expressed by murine HSCs and identifies a proliferative population of HSCs that resides near BM vasculature and retains in vivo repopulating capacity.[106]

Although this chapter focuses on the phenotypic and functional characterization of HSCs, increasing evidence suggests that a subset of adult T-cell progenitors may possess myeloid potential.[107–109] Using various methodologies, Bell et al.[108] and Wada et al.[107] first reported that adult T-cell thymic progenitors possessed myeloid differentiation potential. However, a subsequent study using in vivo transplantation models did not confirm the myeloid potential of adult T cells.[109] De Obaldia et al. reported that the majority of resident granulocytes in the mouse thymus were derived from early thymic progenitors.[110] Mechanistically, it has also been shown that the transcription factor, HES1, constrains myeloid gene expression in T-cell progenitors via repression of C/EPB-α.[111] Taken together, these data suggest that a population of common lymphoid progenitors (CLPs) may indeed possess myeloid differentiation potential.[110,111] Recent studies have also clarified the nature of CLPs and have dissected this population further into an all-lymphoid progenitor cell (ALP), which retains full lymphoid potential and thymic seeding capability, and B lymphoid progenitor cells (BLPs), which are restricted to the B-cell lineage.[112] Whereas ALPs are characterized by the lack of surface expression of LY6D, BLPs express LY6D and upregulate the B-cell-specific factors, EBF1 and PAX5.[112] The phenotypic markers of the hematopoietic hierarchy through myeloid and lymphoid differentiation are shown in Fig. 9.2.

Human Hematopoietic Stem Cells

Significant progress has also been made in the phenotypic characterization of human HSCs via flow cytometric analysis combined with in vivo transplantation assays in immune-deficient mice.[113,114] Of particular note, although murine HSCs can be characterized by the absence of CD34 expression on the cell surface, human HSCs are primarily enriched using CD34 surface expression, and this provides the basis for confirming sufficient HSC content to allow for successful hematopoietic cell transplantation in patients.[17,115,116] There is also some controversy in this area because some investigations have suggested that LT-HSCs can be isolated from CD34$^-$ human hematopoietic cells.[117–120] Of note, only a small percentage (less than 0.1%) of CD34$^+$ human hematopoietic cells possess

the capacity to engraft following intravenous injection into non-obese diabetic/severe combined immune deficient (NOD/SCID) mice.[4,114] Further enrichment of human HSCs has been demonstrated via negative selection for surface expression of CD38 and depletion of lineage surface markers.[114,121,122] Thy-1 (CD90) surface expression also enriches for multilineage colony-forming ability and in vivo reconstituting capacity of human hematopoietic cells.[17,123] Majeti et al. showed that the Lin$^-$CD34$^+$CD38$^-$CD45RA$^-$Thy-1$^+$ population in human CB was enriched at the level of one in 10 cells for LT-HSCs.[123] The authors also showed that candidate multipotent progenitor cells (MPPs) were demarcated by the Lin$^-$CD34$^+$CD38$^-$CD45RA$^-$Thy-1$^-$ population, suggesting that the loss of Thy-1 reflects the transition of LT-HSCs to short-term (ST)-HSCs/MPPs.[17,123]

CD49f$^+$ Human Hematopoietic Stem Cells

Although it is possible to enrich murine BM HSCs to the level of nearly single-cell purity using various combinations of cell surface markers, isolation of human BM HSCs to the same level of purity has not been readily achieved.[89,95,124] However, Notta et al. demonstrated that intrafemoral injection of a fluorescence-activated cell sorting (FACS)-purified population of human CB CD34$^+$CD38$^-$CD45RA$^-$Thy-1$^+$ cells that were additionally purified based on surface expression of the integrin α6 (CD49f) yielded 6.7-fold increased human donor chimerism at 20 weeks in NOD/SCID IL2R$\gamma^{-/-}$ (NSG) mice compared with injection with the identical dose of CD34$^+$CD38$^-$CD45RA$^-$Thy-1$^+$CD49f$^-$ cells.[125] Only the Thy-1$^+$CD49f$^+$ cells could be serially transplanted in this study, and the enrichment for LT-HSCs via limiting dilution analysis was estimated to be approximately one in 11 CD34$^+$CD38$^-$CD45RA$^-$Thy-1$^+$CD49f$^+$ cells.[125] Further purification of this population of cells using Rh123 dye demonstrated that single-cell transplantation of Thy-1$^+$Rh123^{lo}CD49f$^+$ cells yielded LT, multilineage engraftment in five of 18 transplanted recipients. Serial transplantation was also successful in two of four secondary mice, suggesting that at least some of the Thy-1$^+$Rh123^{lo}CD49f$^+$ cells undergo self-renewal.[125] Of note, because mice were transplanted via intrafemoral injection in these studies, it remained unknown whether this panel of markers equally identified human HSCs capable of homing properly to the BM after intravenous injection. Nonetheless, these studies revealed that the addition of CD49f$^+$ to the panel of human LT-HSC markers provided an improved capability to isolate human HSCs at a level of purity that was comparable to that applied to murine HSC isolation.

Two additional novel cell surface markers for human HSCs are CD166 (activated leukocyte adhesion molecule) and protein tyrosine phosphatase-sigma (PTPσ).[126,127] Human Lin$^-$CD34$^+$CD38$^-$CD49f+CD166$^+$ cells engrafted in primary and secondary NSG mice at a significantly higher level than Lin$^-$CD34$^+$CD38$^-$CD49f$^+$CD166$^-$ cells.[126] Interestingly, CD166 is also expressed by BM osteoblasts and it was postulated that CD166 mediated HSC maintenance in vivo via homophilic interactions between CD166 expressed on HSCs and osteoblasts.[126] Quarmyne et al. reported that NSG mice transplanted with human CB Lin$^-$CD34$^+$CD38$^-$CD45RA$^-$PTPσ^- cells displayed 15-fold higher human hematopoietic cell engraftment at 16 weeks compared to mice transplanted with Lin$^-$CD34$^+$CD38$^-$CD45RA$^-$ cells or Lin$^-$CD34$^+$CD38$^-$CD45RA$^-$PTPσ^+ cells.[127] Protein tyrosine phosphatase–sigma (PTPσ) was shown to negatively regulate both murine and human HSC repopulation following transplantation, via inhibition of the RhoGTPase, RAC1.[127] Subsequent studies showed that systemic administration of a small molecule, an allosteric inhibitor of PTPσ to irradiated- or chemotherapy-treated mice promoted the early regeneration of HSCs, white blood cells, and neutrophils in vivo, while ex vivo treatment of irradiated human CD34+ hematopoietic stem and progenitor cells (HSPCs) similarly promoted the rescue of human NSG mice repopulating cells.[128]

Advances in methods to perform single cell transcriptomic, genomic, and proteomic analysis have led to several studies characterizing the molecular profile of single human HSCs.[129–135] These studies have revealed remarkable heterogeneity within phenotypically identical human HSCs in steady state and in response to growth factor treatment and have shown that HSC fate determinations can be related directly to expression levels of lineage-specific transcription factors.[136,137] Single cell analysis of HSCs from aging donors revealed age-associated epigenetic reprogramming within cancer and developmental pathways, suggesting the basis for increased incidence of acute myeloid leukemia (AML) with aging (see Chapters 13 and 19).[138] Continued progress in the molecular and functional characterization of single human HSCs will undoubtedly lead to much improved definition of the human hematopoietic hierarchy and the more optimized selection of purified human HSCs for transplantation.

Functional Characterization

In Vitro Assays

The colony-forming cell (CFC) assay does not measure HSC content but rather committed myeloid progenitor cell content via a 14-day assay for colonies within methylcellulose media that is supplemented with specific growth factors.[93] The CFC assay measures colony-forming unit-granulocyte/macrophage (CFU-GM), burst-forming unit-erythroid (BFU-E), and CFU-granulocyte/erythroid/macrophage/megakaryocyte (CFU-GEMM). The CFU-GEMM, or CFU-mix colonies, represent a more immature progenitor cell population. B- and T-cell progenitor cell content can also be measured via in vitro assays but requires specialized coculture conditions, which are described elsewhere.[93,139,140]

The LT culture-initiating cell (LTC-IC) assay is a 6-week in vitro assay in which BM cells are cocultured with murine stromal cells for four weeks followed by replating of the entire culture system into methylcellulose and additional two-week assay for colony formation.[93,141] The LTC-IC, unlike the CFC, measures a more immature stem/progenitor cell population, although the results of the LTC-IC are inherently dependent and limited by technical variabilities in stromal coculture experiments.[93] Importantly, the LTC-IC population lacks LT repopulating cells because transplantation of LTC-ICs into mice in a competitive transplantation assay does not result in any LT reconstitution.[93,113,114]

The cobblestone area-forming cell (CAFC) assay also involves coculture of HSCs with pre-established stromal cell monolayers and relies on microscopic quantification of cobblestone-forming cells embedded underneath the stromal layer.[141,142] It has been shown that CAFC content correlates well with CFU-S content on day 12 and marrow repopulating capacity.[93,141] However, similarly to the LTC-IC, the CAFC assay does not measure LT-HSCs. An advantage of the CAFC and LTC-IC assays is that the estimate of stem/progenitor cell content is not confounded by the homing capacity of the cell population being tested. However, competitive transplantation assays provide a more physiologically relevant measure of functional HSC content and allow quantification of LT-HSC content as well as homing efficiency.[79,93,143]

In Vivo Assays

Colony-Forming Unit–Spleen Assays

The first reproducible in vivo assay for hematopoietic progenitor cells (HPCs) was the CFU-S assay, which was developed by Till and McCullough.[12,113] In this assay, BM cells are injected into lethally irradiated mice, and macroscopic spleen colonies are measured from one to three weeks after injection.[93] These colonies represent ST repopulating cell and MPP activity but do not measure LT-HSC content.[4,93]

Competitive Repopulation Assays

A significant advance in the study of hematopoiesis was the development of the competitive repopulating assay (Fig. 9.3).[93,144] In this assay, an unknown population of hematopoietic cells is transplanted via intravenous injection into lethally irradiated syngeneic mice along with a competing dose of host-derived BM cells.[93,145,146] This assay has been refined over time such that it is typically performed using a limiting dilution method in which several cell doses (typically more than three to five doses; $n = 10$ mice/dose level) of BM cells or purified HSCs (e.g., CD34$^-$KSL cells) are injected into lethally irradiated mice along with a fixed dose of host competitor BM cells, such that a fraction of the recipient mice can be predicted to have nonengraftment.[93,147,148] This approach allows the application of Poisson statistical analysis to provide an estimate of competitive repopulating units (CRUs) within the donor hematopoietic cell population.[93,147–149] An important feature of the CRU assay is the potential to estimate the frequency of LT-HSCs in a given hematopoietic cell population. Donor cell engraftment that is detected within the first 8 to 12 weeks after transplantation reflects the contribution of ST-HSCs, which extinguish at or beyond 12 weeks posttransplant. Therefore, the number of LT-HSCs cannot be convincingly estimated until more than 12 to 20 weeks posttransplantation.[93,150] Dykstra et al.[151] showed that competitive transplantation of single, phenotypic HSCs results in stable donor cell engraftment in lethally irradiated mice beyond 16 weeks, and retroviral marking of HSCs revealed that stable donor-derived hematopoiesis was not observed in recipient mice until six months posttransplant.[150]

A commonly used and rigorous approach to estimate the presence of LT-HSCs is the performance of secondary, tertiary, and quaternary HSC transplants.[93] This approach is based on the principle that a singular feature of primitive LT-HSCs is the capacity to serially reconstitute multilineage hematopoiesis in vivo without exhaustion.[93,152–154] In this method, whole BM is typically collected from primary recipient mice and then injected, along with host competitor BM cells, into lethally irradiated syngeneic mice. Donor cell repopulation is then measured at 12 to 20 weeks post transplantation. Serial transplantation assays have the limitation of being potentially confounded by variables such as homing efficiency of the donor cells.[93,155,156] Therefore, as pointed out by Purton and Scadden[93] in an excellent review of this subject, serial transplantation assays may be better suited to studies of wild type hematopoietic cell populations as opposed to mutant mice-derived hematopoietic cells, which may have alterations in homing or engraftment mechanisms independent of HSC content.[93] Utilization of whole BM avoids issues regarding the fidelity of phenotypic markers of HSCs in mutant mice and is perhaps more broadly feasible than FACS-isolated HSC populations at

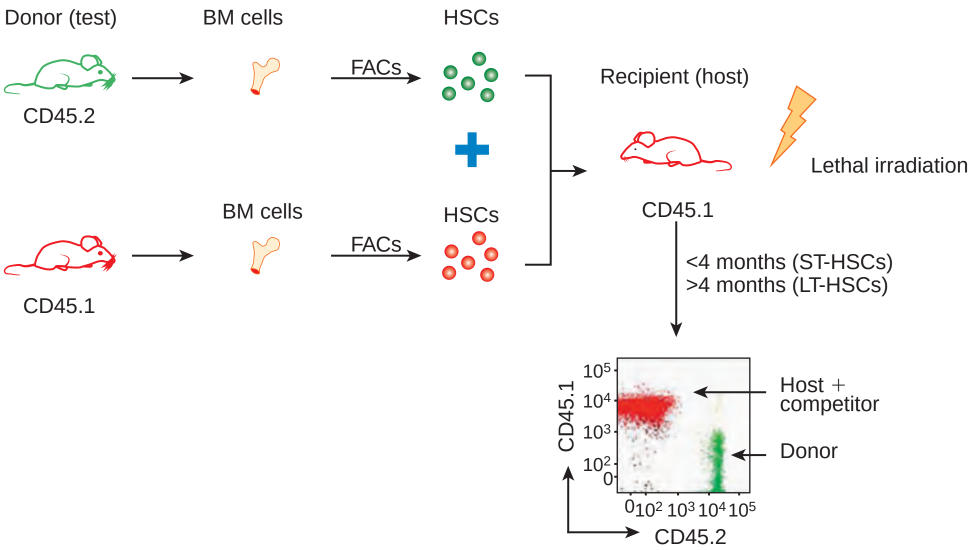

Figure 9.3 COMPETITIVE REPOPULATION ASSAY. Bone marrow (BM) cells from donor mice carrying the CD45.2 allele are sorted by fluorescence-activated cell sorting (FACS) and transplanted with an excess of BM cells from CD45.1 mice into lethally irradiated CD45.1 recipient mice. In general, three to four months posttransplantation, peripheral blood cells are analyzed by flow cytometry to identify the fraction of donor CD45.2 BM cells that, if present, must have homed to and engrafted the myeloablated recipient mouse. While short-term hematopoietic stem cells (ST-HSCs) do not persist in the recipient mouse after four months, long-term (LT)-HSCs are defined by their presence in the recipient mouse after four months and the ability to repopulate secondary, tertiary, and quaternary recipients. *(Adapted from http://stemcellassays.com/2011/11/experimental-bone-marrow-transplantation-101-%E2%80%93-part-2-congenic-mouse-model/.)*

some centers.[93,157–160] However, the use of purified HSCs avoids the potential confounding effects of accessory cells contained within the BM graft on donor cell repopulation and allows for precise determination of effects of growth factors on HSC content in vitro compared with un-manipulated BM.[139,161] Lastly, Poisson statistical analysis and estimation of CRU frequency is based on particular criteria for "positive" donor engraftment in recipient mice, typically 0.1% to 1% multilineage donor engraftment.[139,162] Therefore, the estimation of CRU frequency can be substantially altered depending on what criteria for engraftment are utilized. Given the limitations of flow cytometric analysis for accurate multilineage engraftment of hematopoietic cells, it is recommended that greater than 1% multilineage engraftment is used as a criterion for evidence of donor cell repopulation using the competitive repopulating assay.[93]

Clonal Dynamics of Hematopoietic Stem Cells

Historically, the transplantation assay, in which prospectively purified cell populations are transplanted into myeloablated recipients, has served as the "gold standard" for testing BM compartments for HSC potential. Under optimal conditions, a single HSC can reconstitute the entire hematopoietic system of the host.[78,84,95,151,163] Based on initial transplantation studies, HSCs have been fitted into a simple linear branching hierarchy.[164] Such a hierarchical model assumes that all HSCs have similar developmental potential and, when committed to differentiate, can give rise to both a myeloid and lymphoid progenitor with equal probability. However, tracking experiments with individual retrovirally marked HSCs have revealed extensive heterogeneity within the HSC pool,[150,152,165,166] which was subsequently confirmed by limiting dilution transplantation.[78,163,167–171] Several models have been proposed to explain how diversity in HSC functionality is generated. These are broadly separated into instructive and intrinsic regulation models. According to the instructive models, each HSC is provided with slightly different cues from the microenvironment in which it resides.[172–174] On the other hand, intrinsic regulation of HSC heterogeneity is either completely unpredictable (stochastic)[175–178] or "programmed" (deterministic).[171,179]

The development of methods to obtain highly purified HSCs by FACS has permitted single-cell transplants that address the basis of heterogeneity.[151,163,180–183] Some of these studies demonstrate the existence of myeloid and lymphoid "biased" HSCs and that LT repopulation is dependent on sustained myeloid reconstitution, irrespective of a contribution to the lymphoid compartment. Other studies using various combinations of phenotypic markers and FACS with functional single-cell in vitro or transplantation assays and single-cell expression profiling identified stem-like megakaryocyte-committed progenitors in the HSC compartment in mice.[183–185] In addition, single-cell gene expression profiling of index-sorted mouse or human HSPCs confirmed that unipotent progenitors directly emerge from a continuum of immunophenotypically highly interconnected HSPCs.[186,187] HSCs are also heterogeneous in their response to extrinsic signals such as transforming growth factor-β1 (TGF-β1).[181,188] Importantly, it has been observed that HSC "heterogeneity" is stably propagated to recipients upon secondary transplantation.[151,189,190] This finding argues for some intrinsic regulation in which all HSCs in a clone follow a predetermined fate that is preset earlier in development.

Hematopoiesis as analyzed by transplantation is generally oligoclonal, that is, only few of the transplanted HSC clones contribute to multilineage repopulation.[150,152,191,192] These results have argued for a "clonal succession" model of stem cell activation which posits that a small number of HSCs are sequentially activated from a pool of otherwise noncycling quiescent cells, but that these HSCs exhaust and are replaced over time.[150,193,194] In contrast, the "clonal stability" model states that many or all HSCs have a low but constant cell cycle activity allowing them to continuously contribute to an organism's blood life-long. Support for this model is derived from experiments showing that after transplantation a few HSC clones persist for a long time.[177,195,196] HSCs could also follow the behavior predicted by both models as other studies have shown that HSCs may reversibly switch between the quiescent and a self-renewal state in a homeostatic environment or when challenged by injury, respectively.[197–199]

A general limitation to transplantation approaches is their dependence on HSCs that home to and engraft a niche, proliferate rapidly, and tolerate the stress imposed by the engraftment and an unbalanced cytokine milieu in myeloablated niches. Intriguing studies employing novel genetic labeling strategies in the mouse have explored native, unperturbed hematopoiesis and have demonstrated that, in this setting, steady-state hematopoiesis appears to rely predominantly on long-lived progenitors rather than HSCs.[200–202] While these results have been debated, they argue for the dominant contribution of MPPs or ST-HSCs to hematopoiesis in the untransplanted mouse. Thus, in contrast to the transplantation setting, native hematopoiesis could be highly polyclonal, supported by the successive recruitment of thousands of clones and as such fits the clonal succession model. Why more restricted progenitors, such as ST-HSCs or MPPs, cannot repopulate the hematopoietic system after transplantation is unknown but presumably relates to the ex vivo handling of cells for transplantation or the stress of increased proliferation following transplantation. Furthermore, while it is commonly thought that in myeloid malignancies the "cell of origin," which acquires the first cancer-promoting mutation,[203] is an HSC because of their extended lifespan, these recent studies suggest that long-lived progenitors might be equally suitable candidates for tumor-initiating cells.[201]

Simultaneous tracing of lineage fates and gene expression profiling of single HSPCs has confirmed the existence of uni-lineage clones and revealed that the megakaryocyte can be the primary product of LT-HSCs.[204] More recently, these efforts have been taken a step further in the form of genetically engineered mouse models that can also track cell ancestry information.[205,206] This strategy has revealed four classes of HSC clones operational during native hematopoiesis: differentiation inactive, myeloerythroid restricted, myeloerythroid biased, and multilineage clones.[206] This study also for the first time investigated the relationship between HSC dormancy and cell cycle activity in unperturbed hematopoiesis.[206] Interestingly, differentiation-active HSCs were found with a transcriptional signature characteristic of dormant HSCs. At the same time, differentiation-inactive HSC clones were comprised of cycling cells, suggesting that they contribute to HSC maintenance by self-renewal, which is consistent with other data showing that even the most quiescent HSCs still display low levels of proliferation.[207,208] The approach of studying unperturbed clonal hematopoiesis is rapidly evolving, and future studies will be needed to comprehensively interrogate all HSC fates at steady-state and under perturbation.

REGULATION OF HEMATOPOIETIC STEM CELL FATE

HSCs have the capacity to generate more stem cells, a process called self-renewal, and to produce cells that differentiate into the entire spectrum of mature hematopoietic cells. The balance between these fate choices is thought to be regulated by the type of cell division that HSCs undergo.[209] Asymmetrical cell divisions result in one HSC (self-renewal) and one committed HPC, allowing the maintenance of the stem cell pool while concomitantly ensuring the supply of differentiated cells. However, during development and regeneration the stem cell pool must have the capacity to expand. This can be achieved by symmetrical cell divisions, which will lead to two daughter HSCs capable of self-renewing. Another outcome of symmetric division would be two HPCs, diminishing and ultimately exhausting the HSC pool. The fate decision governing this balance between self-renewal and differentiation is regulated by cell-intrinsic mechanisms including transcriptional and epigenetic mechanisms that are intertwined with cell-extrinsic mechanisms from the microenvironment or by the action of systemic factors.

Extrinsic Regulation

In the adult, HSCs reside in a complex microenvironment or niche, in close association with vascular ECs, perivascular stromal cells, osteoblasts and bone progenitor cells, sympathetic neurons, and other mature hematopoietic cells, such as megakaryocytes and macrophages.[210,211] HSC maintenance, self-renewal, regeneration, and malignant transformation are all necessarily impacted by extrinsic regulation by niche elements.[210,211] The precise contributions of BM niches in regulating HSC fate are described in detail separately in Chapters 11 and 14. Here, we will focus on select extrinsic mechanisms that have been validated to have fundamental roles in regulating HSC fate.

NOTCH Signaling

The NOTCH signaling pathway has been shown to have an important role in regulating the development of the central nervous system, eye, muscle, hematopoietic system, and germline, among others.[212,213] To date, four NOTCH receptors have been identified (NOTCH1–4) as well as five ligands for Notch receptors (JAGGED1 and 2 and DELTA1, 3, and 4).[214] Ligand receptor interaction on HSCs induces two NOTCH cleavage steps, the last of which is mediated by γ-secretase and releases the constitutively active NOTCH-intracellular domain (NICD). The NICD then translocates to the nucleus, interacts with the DNA-binding protein RBPJ (recombination signal binding protein for immunoglobulin kappa J region), and initiates transcription of target genes such as the transcription factors HES1 and HES5 (mammalian homologues of Drosophila hairy and Enhancer of split).[215–218] Depending on the specific NOTCH ligand, different NOTCH receptors and thus different NOTCH target genes are activated, leading to diverse cellular outcomes. For example, NOTCH1 activation by Delta1 and 4 is required for T-cell differentiation while it inhibits differentiation of the B-cell lineage. Jagged2- or Delta1-mediated activation of NOTCH2 inhibits myeloid differentiation and induces the generation of LT-HSCs and MPPs.[216,219]

Activation of NOTCH signaling is sufficient to induce ex vivo HSC expansion. Retroviral expression of the *Notch1* ICD in murine HSCs leads to the generation of an immortal, cytokine-dependent cell line with multilineage in vivo repopulating capacity,[220] and immobilized Delta1 promotes a several-log expansion of murine HSC cultures.[221] Furthermore, Jagged2-mediated activation of NOTCH signaling inhibits the differentiation of human CB CD34$^+$ cells,[222] and culture of human CB HSCs with soluble human Jagged1 induces HSC expansion ex vivo.[223] NOTCH ligands that are expressed in the surrounding BM niche are thought to be critical in promoting HSC maintenance through the activation of NOTCH receptors expressed on HSCs. For example, BM osteoblasts express *Jagged1* and blocking NOTCH activation with a γ-secretase inhibitor significantly decreases murine HSC expansion in BM osteoblast cocultures.[224] Similarly, sinusoidal ECs that express NOTCH ligands stimulate expansion of wild-type but not *Notch1*$^{-/-}$*Notch2*$^{-/-}$ LT-HSCs in vitro.[225] However, although deletion of *Jagged1*, *Notch1*, or *Rbpj* results in impaired embryonic hematopoiesis in the mouse, the physiologic role of NOTCH signaling in the maintenance of the adult HSC pool in vivo is controversial.[224] Deletion of *Jagged1* was shown to have no effect on HSC content in mice,[226] and deletion of *Rbpj* did not cause a defect in HSC repopulating capacity.[227] Interestingly, while neither *Notch1* nor *Notch2* were found to be required for HSC function under homeostatic conditions in vivo,[219,226] challenging the BM with chemotherapy or radiation in the presence of a conditional *Notch2* deletion resulted in more rapid myeloid differentiation at the expense of HSC self-renewal.[219]

In keeping with the evidence obtained from mouse studies that activation of NOTCH signaling can induce HSC expansion, Delaney et al.[228] showed that serum-free culture of human CB progenitor cells with immobilized Delta1 plus cytokines for three weeks yielded a 5.3-fold increase in human hematopoietic cell engraftment in transplanted NOD/SCID mice. This group subsequently completed a phase I clinical trial showing that transplantation of CB cells, which had been expanded with immobilized Delta1 along with an unmanipulated CB unit shortened the time interval to neutrophil recovery (median, 16 days) compared with a cohort that received two un-manipulated CB units (median, 26 days).[229] Of note, in this phase I study, the un-manipulated CB cells demonstrated dominant engraftment by day 80 after transplant and in seven of eight reported recipients, ex vivo expanded CB cells were not detectable in recipients by day 40 posttransplant.[229] The extinction of the Delta1-expanded CB units might be explained by T-cell depletion as donor CB CD8$^+$ T cells of a successful graft have been shown to mediate the rejection of the other CB unit in the setting of double CB transplantation.[230]

WNT Signaling

Wingless-related integration site (WNT) signaling is initiated by the interaction of WNT ligands with the so-called Frizzled/ lipoprotein receptor-related protein (LRP) cell surface receptor complex. In the absence of ligand binding, the WNT signal transducer β-catenin is phosphorylated by kinases such as glycogen synthase kinase-3 beta (GSK-3β), leading to its rapid degradation. Upon activation of the canonical WNT pathway, β-catenin is no longer phosphorylated and thereby stabilized, translocates into the nucleus and interacts with transcription factors of the T-cell factor/lymphoid enhancer factor (LEF/TCF) family to regulate expression of target genes.[231] Several lines of evidence implicate WNT signaling in the regulation of HSC self-renewal and differentiation. First, WNT proteins have been shown to be expressed at sites of embryonic and fetal hematopoiesis, and WNT ligands, receptors, and LEF/TCF transcription factors are expressed by adult HSCs as well as components of the BM microenvironment.[232,233] Second, ample evidence suggests that activation of WNT signaling is capable of promoting HSC expansion, at least in vitro.[234–238] Using mice transgenic for human *BCL2* enabling HSCs to survive in the presence of stem cell factor (SCF) alone,[239,240] treatment of BMKTLS cells with purified WNT3A protein or transduced with active β-catenin ex vivo resulted in their expansion and multilineage reconstitution of competitively transplanted recipients.[234,238] In a related study, treating immune-deficient recipient mice with a GSK-3β inhibitor after transplantation of lineage-depleted human CB HSCs increased their engraftment and repopulating capacity, which was accompanied by faster recovery from post-transplant cytopenias.[241] Importantly, WNT-mediated maintenance of the HSC pool was demonstrated to depend on intact NOTCH signaling,[242] suggesting a deterministic role for the NOTCH pathway in controlling the effects of WNT signaling on the undifferentiated HSC pool.[243] On the other hand, HSCs from mice engineered to conditionally express a stable form of β-catenin had a block in differentiation and failed to self-renew leading to their exhaustion.[244,245] These results raise the possibility that the prior report of HSC expansion in response to β-catenin overexpression may have been affected by the use of *Bcl2* transgenic mice.[234] Alternatively, WNT signaling might have a more pronounced role in vitro than in the more complex in vivo setting.[237]

Some WNT ligands, for example, WNT5A, are able to activate pathways other than the canonical WNT pathway, depending on the particular WNT receptor context.[246] In vivo activation of non-canonical WNT signaling via systemic administration of WNT5A was shown to induce a greater than threefold increase in human CB HPC repopulation in NOD/SCID mice.[235] More recent studies have demonstrated noncanonical WNT signaling in the BM niche is required for HSC maintenance in vitro and in vivo.[247,248] Interestingly, it was shown that *Wnt5a* expression is increased in aging LT-HSCs. Induction of *Wnt5a* in young mice induced aging-associated HSC phenotypes, including apolarity, decreased repopulation capacity, and myeloid bias. Conversely, knocking down *Wnt5a* in old mice attenuated HSC aging.[249]

Although activation of WNT signaling can induce HSC expansion, it is uncertain whether WNT signaling is indispensable for normal hematopoiesis to occur. Conditional deletion of β-catenin in adult BM progenitors did not impair their ability for multi-lineage reconstitution.[250] In support of these results, hematopoietic cell ablation of porcupine, a membrane-bound *O*-acyl transferase essential for WNT ligand secretion and receptor interaction, had no effect on proliferation, differentiation, and self-renewal of adult HSCs in vivo.[251] Conversely, embryonic conditional knockout of β-catenin caused a deficiency in self-renewal of murine LT-HSCs,[252] and HSCs derived from *Wnt3a*$^{-/-}$ mice failed to repopulate secondary recipients,[253] suggesting that WNT signaling might have different roles in embryonic versus adult HSCs.

Transforming Growth Factor-β and Hedgehog Signaling

The TGF-β pathway represents a signaling mechanism that can be activated by members of the TGF-β superfamily including TGF-β, activins, and bone morphogenetic proteins (BMPs).[254] Each of these ligands binds to a specific receptor heterodimer composed of a type I and II receptor, leading to the phosphorylation of a subset of the receptor-regulated SMAD proteins (R-SMADs: SMAD1, 2, 3, 5, and 8). Thus activated R-SMADs then form a complex with the common SMAD SMAD4, and translocate into the nucleus to co-regulate target gene transcription. Another class of SMADs, inhibitory SMADs (SMAD6 and 7) block TGF-β family signaling by binding to R-SMADs.

TGF-β is one of the most potent inhibitors of HSC proliferation in vitro, and neutralization of TGF-β releases HSCs from quiescence.[255–257] It has been suggested that TGF-β mediates cell cycle inhibition in HSCs via upregulation of cyclin-dependent kinase inhibitors, p21, p27, and p57, as well as downregulation of cytokine receptors.[258–262] The role of TGF-β in vivo appears to be more complex. TGF-β likely functions as a negative hematopoietic regulator in vivo as supported by the observation that deletion of TGF-β1 results in extensive myelopoiesis in mice[263] as well as defective homing of HSCs.[264] Moreover, HSCs from mice with a conditional deletion of the TGF-β type II receptor show increased cell cycling and impaired repopulation capacity.[265] Conversely, TGF-β type I receptor null mice display normal HSC self-renewal and regeneration in vivo, although these HSCs exhibited increased proliferation in vitro.[266,267] The discrepancies between different knockout phenotypes could be caused by differences in expression levels of the TGF-β receptors in HSCs and thus their different in vivo importance.[258] Still, TGF-β is considered a critical signal for HSC quiescence in vivo.[258]

BMP signaling is required for mesoderm formation and patterning, and BMPs are key regulators for the hematopoietic specification from mesoderm across different species (reviewed in Ref. 254). BMP4 has been shown to modulate adult human HSC maintenance and proliferation in a concentration-dependent manner, with high BMP4 levels extending the survival of hematopoietic repopulating cells in ex vivo cultures.[268] However, in vivo, BMP signaling does not seem to be required for adult HSC function as determined in mouse knockouts for its signal transducers, SMAD1 and 5.[254] On the other hand, complete inhibition of the SMAD network has demonstrated the importance of SMAD proteins in regulating HSC self-renewal in vivo. Conditional deletion of *Smad4* in mice led to a significantly reduced ability of HSCs to repopulate primary and secondary recipients.[269] Also, retrovirus-mediated overexpression of the inhibitory *Smad7* promoted HSC self-renewal in vivo.[270] Taken together, these results have been interpreted to indicate that SMAD4 positively regulates HSC self-renewal independently from its role as a mediator of SMAD pathway signaling. This hypothesis is supported by evidence demonstrating that SMAD proteins can activate WNT signaling,[271,272] which has been shown to promote HSC expansion as discussed earlier.

As in other species and developmental contexts,[273–275] an intersection between BMP4 and Hedgehog signaling has been described in the human hematopoietic system. Hedgehog proteins play an essential role in the embryonic development of a wide variety of organs, and, like BMPs, they are required for mesoderm patterning.[276,277] Culturing of human CB progenitor cells with Sonic Hedgehog (SHH), one of three human Hedgehog proteins,[278,279] promoted the expansion of cells capable of multi-lineage repopulation in NOD/SCID mice.[280] The addition of Noggin, an endogenous inhibitor of BMP4, blocked the effect of SHH on CB stem cell proliferation in vitro, whereas Hedgehog inhibition did not block BMP4-induced HSPC proliferation, suggesting that BMP4 acts downstream of *SHH* in the regulation of human HSC growth.[280] Several other studies suggest that hedgehog signaling regulates HSC growth. Mice heterozygous for the Hedgehog antagonist Patched1 (*Ptc1*) were shown to have an expanded HSC compartment[281] and their fetal

HSCs exhibited increased colony-forming potential in serial plating assays.[282] Interestingly, while conditional deletion of the Hedgehog effector Smoothened (*Smo*) resulted in a profound loss of LT-HSCs in the embryo,[283] conditional deletion of *Smo* or pharmacologic inhibition of Hedgehog had no effect on HSC content or hematopoiesis in adult mice.[284,285] Thus, Hedgehog signaling during embryogenesis might be required for certain aspects of HSC function important in adult life.[286]

CXCL12–CXCR4 Signaling

CXCL12 is a chemokine that is expressed by BM osteoblasts, ECs, and perivascular stromal cells in the BM microenvironment and regulates the homing and retention of HSCs.[287–289] Expression of CXCL12 or its receptor, CXCR4, is necessary for HSC maintenance in vivo.[288–290] Ding et al. reported that deletion of *Cxcl12* from perivascular stromal cells or vascular ECs depleted HSCs in mice, whereas depletion of *Cxcl12* from nestin$^+$ mesenchymal cells or osteoblasts had no effect on HSC numbers.[288] Greenbaum et al. also showed that deletion of *Cxcl12* in *Prx1*-expressing perivascular stromal cells led to HSC depletion,[291] confirming the importance of CXCL12 signaling in the perivascular niche for HSC maintenance. A more detailed review of CXCL12-CXCR4 signaling in the context of the BM microenvironment, as well as a comprehensive review of HSC-HSC niche signaling interactions,[292] are presented in Chapters 11, 12, 14, and 16.

Intrinsic Pathways

Transcription Factors

Transcription factors are proteins that bind specific sequences of DNA within promoter or enhancer regions to regulate the process of transcribing DNA into RNA.[293] Because the intrinsic phenotype or state of a cell is the result of its gene expression, it is governed by the concerted action of transcription factors (guided by the epigenetic landscape discussed further below). The balance between self-renewal and differentiation of HSCs is intricately regulated by transcription factors of many different classes.[294] Several general principles have emerged. First, given the relative limited number of transcription factors, they are used at multiple stages in development, such that they may be required in HSCs and also subsequently in lineage differentiation.[18] Second, the balance between self-renewal and lineage commitment is thought to be regulated, at least in part, by the antagonism of lineage-specific transcription factors. To promote a given lineage, transcription factors need to actively counteract a factor or factors supporting other cell fates. Third, and most relevant to clinical situations, most hematopoietic transcription factors are subject to somatic mutation and/or chromosomal translocation in one or more hematopoietic malignancies. Thus, malignancy can be viewed as a disruption of normal development. Fig. 9.2 depicts key transcription factors within the hematopoietic hierarchy, and Table 9.1 summarizes main roles of critical transcription factors in HSPCs and hematologic malignancies.

Transcription Factors Required for the Specification of Hematopoietic Stem Cells

As one of the few transcription factors known to be essential for the mesoderm-hemangioblast transition, the ETS class protein ETV2 is expressed in a subset of FLK1$^+$ cells with enhanced endothelial and hematopoietic potential and downregulated thereafter.[295,296] Together with the forkhead transcription factor FOXC2, it cooperatively induces the FLK1$^+$ mesoderm by stimulating the expression of key endothelial and hematopoietic genes such as *Flk1*, *vascular endothelial* (*VE*)*-cadherin*, *Tie2*, *Scl*, and *Notch4*.[297]

Before the emergence of HSCs, the bHLH protein SCL is required for the specification of the bipotent hemogenic endothelium within the hemangioblast during embryonic development.[298] Its knockout in mice, as well as that of its binding partner LIM domain protein *Lmo2*,[299–301] results in the absence of hematopoiesis resulting in early embryonic lethality,[302–305] and an absence of adult HSCs.[306,307] SCL expression is regulated by three hematopoiesis-specific enhancers, one of which comprises an ETS/ETS/GATA motif that binds ETS transcription factors FLI1 and ELF1 as well as GATA2, revealing the transcriptional cascade at the top of the hematopoietic hierarchy.[308] Interestingly, once emerged, HSCs require either SCL or the closely related bHLH factor LYL1 for function and survival.[309–311] Elevated expression of *SCL* and/or *LMO2*, as well as *LYL1*, is found in 35% to 65% of T-cell acute lymphoblastic leukemias (see Chapter 66) (T-ALL), mostly because of chromosome translocations but also, in the case of *SCL*, intragenic deletions.[312]

GATA2, a zinc finger transcription factor, is expressed before HSC emergence in the paraaortic splanchnopleura and later in the AGM.[313] GATA2 has been shown to be essential for the production of cells belonging to all lineages in definitive (or adult) hematopoiesis.[314,315] Interestingly, it functions to preserve the pool of immature HSPCs by preventing the differentiation of hematopoietic precursor cells.[316] Thus, reduction of *GATA2* expression or activity is a prerequisite for HSC commitment. Heterozygous germline mutations in *GATA2* are the cause of several clinical syndromes (see Chapter 49): MonoMAC (monocytopenia and *Mycobacterium avium* complex infections),[317,318] which is also described as dendritic cell, monocyte, and lymphoid deficiency (DCML).[319,320] Individuals with MonoMAC almost invariably progress to a distinct form of myelodysplastic syndrome (MDS) and in 14% and 8% to AML or chronic myelomonocytic leukemia (CMML), respectively.[321] Familial myelodysplastic and AML syndrome[322] as well as Emberger syndrome (primary lymphedema with predisposition to AML)[323] also belong to this group, and in some cases are caused by the identical *GATA2* mutation.

The core-binding protein RUNX1 and its obligate binding partner CBF-β are both required for the transition from hemogenic endothelium to definitive HSCs.[324–327] *Runx1* expression is upregulated during the EHT in the hemogenic endothelium, probably by GATA2, the ETS transcription factors FLI1 and PU.1, and the SCL complex (SCL, LMO2, LDB1).[328] RUNX1 then induces expression of other critical transcription factors such as GFI1 and GFIB which in turn downregulate the endothelial markers TIE2, VE-cadherin, and KIT.[329] In addition, RUNX1 causes rapid global reorganization of transcription factors such as SCL, FLI1, and C/EBPβ which is critical for the EHT and hematopoietic fate.[330] RUNX1 is also required to antagonize the effects of the homeobox transcription factor HOXA3, a negative regulator of specification of the hemogenic endothelium. HOXA3 represses a cascade of transcription factors that promote hemogenesis while at the same time inducing a set of genes critical for maintaining endothelial character.[331] *RUNX1* and *CBF-β* are the most common target of chromosomal translocations in acute leukemia. In particular, translocations resulting in *RUNX1-ETO* and *CBF-β-MYH11* cumulatively account for 15% of AML.[332] Consistent with the fact that neither *RUNX1-ETO*[333] nor *CBF-β-MYH1*[334] induce leukemia by themselves in mouse models but rather require additional mutations, next-generation sequencing studies have identified both as preleukemic lesions.[335,336] In addition, mutations in *RUNX1* are observed in patients with various hematologic diseases including MDS, CMML, ALL, de novo and therapy-related AML, and the autosomal dominant preleukemic syndrome familial platelet disorder with predisposition to AML (FPD/AML).[337]

Transcription Factors Required for Hematopoietic Stem Cell Homeostasis

Many transcription factors from different protein classes that play a role in setting up the hematopoietic hierarchy are necessary for HSC self-renewal in competitive transplantation assays.[1] For example, SCL is expressed much higher in LT-HSCs compared to ST-HSCs, and promotes their quiescence,[338] which preserves the LT-HSC pool.[339] In HSCs as well as differentiating progenitors, SCL exists in different complexes most of which include GATA2 (or GATA1 in the erythroid lineage), E2A, and the non-DNA binding adaptor proteins LMO2 and LDB1.[328,340] Loss of any of these SCL partners leads to

TABLE 9.1 **Roles of Critical Transcription and Epigenetic Factors Involving Hematopoietic Stem and Progenitor Cells in the Development of Hematologic Malignancies**

	Requirement in HSPCs[a]	Type of Alteration	Disease	Reference
Transcription Factor				
SCL (TAL-1)	Mesoderm-endothelial/hematopoietic lineage transition; MegE lineage differentiation	Chromosomal translocations involving *TCR* genes; *SIL-TAL1* fusion gene; aberrant expression for other reasons	T-ALL	245, 263, 533
LMO2	Primitive erythropoiesis; generation and maintenance of definitive HSCs	Chromosomal translocations involving *TCR* genes; interstitial deletion; aberrant expression for other reasons	T-ALL (B-cell lymphoma; B-ALL; X-SCID gene therapy associated T-cell leukemia)	533, 534
GATA2	EHT; HSC survival and self-renewal; MegE, mast cell, monocyte lineage differentiation	Mutations	MonoMAC, MDS, AML, CMML, Emberger syndrome	535
RUNX1 (AML1, CBF-α)	Formation of intra-aortic clusters and HSCs during EHT; lymphopoiesis	*RUNX1-ETO* chromosomal translocations; mutations	AML	288, 299, 536
CBF-β (CBFB)	Emergence of HSCs from HE (in complex with RUNX1)	*CBF-β-MYH11* chromosomal translocations	AML	288, 537, 538
E2A (TCF3)	Maintenance of adult LT-HSC; LMPP, CLP, early thymocyte progenitor, pro-B-cell differentiation	*E2A-PBX1* chromosomal translocations; mutations	Pre-B-cell ALL; T-cell lymphoma	245, 539
ETV6 (TEL)	Maintenance/survival of adult LT-HSCs	*ETV6-RUNX1* chromosomal translocations; mutations	Pre-B-cell ALL; immature adult T-ALL	297, 299, 539, 540
MYB (C-MYB)	Self-renewal and multilineage differentiation of adult LT-HSCs	Chromosomal translocation involving TCRβ; duplication	T-ALL	541–543
EVI1	Generation of definitive HSCs; Self-renewal of adult LT-HSCs	Aberrant expression; Chromosomal translocations involving *RUNX1* and *ETV6*	AML; MDS, CML blast crisis	246, 544
Epigenetic Factor				
MLL	Generation of definitive HSCs; adult HSC quiescence and self-renewal	Chromosomal translocations involving *AF4*, AF9, *ENL*, *AF10*, *ELL*, *AF6*, etc. (79)	ALL, AML	545, 546
DNMT3A	HSC differentiation	Mutations	AML, T-cell leukemia and lymphoma, MDS	348
TET2	HSC differentiation	Mutations, *IDH1/2* mutations	CMML, AML, MDS, T-cell lymphoma, DLBCL	547, 548
ASXL1	HSC differentiation	Mutations	CMML, AML, MDS	359, 549, 550

[a]Data from complete or conditional knockout studies in mice.

AML, Acute myeloid leukemia; *B-ALL*, B-cell acute lymphoblastic leukemia; *CML*, chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *DLBCL*, diffuse large B-cell lymphoma; *EHT*, endothelial-to-hematopoietic transition; *HE*, hemogenic endothelium; *HSC*, hematopoietic stem cell; *HSPCs*, hematopoietic stem and progenitor cells; *IDH1/2*, isocitrate dehydrogenase 1 and 2; *LMPP*, lymphoid primed multipotent progenitors; *LT*, long-term; *MDS*, myelodysplastic syndrome; *MegE*, megakaryocyte/erythrocyte; *MLL*, mixed-lineage leukemia; *MonoMAC*, monocytopenia and *Mycobacterium avium* complex infections; *SIL*, *SCL* interrupting locus; *T-ALL*, T-cell acute lymphoblastic leukemia; *X-SCID*, X-linked severe combined immunodeficiency.

defects in HSC maintenance.[304,311,341–343] Apart from GATA2 and LMO2, deregulation of E2A also causes hematologic malignancies. Six percent of all pediatric ALLs, in particular pre-B-cell ALL (23%), are caused by a chromosomal translocation that fuses the *E2A* gene with *PBX1* (pre-B-cell leukemia homeobox 1),[344,345] which encodes an important HOX interacting factor discussed later.

The ETS-related transcriptional repressor TEL/ETV6 is specifically required for HSC survival but not their emergence.[346] Like E2A, ETV6 is also involved in chromosomal translocations; the *ETV6-RUNX1* is the most common fusion gene in pediatric cancers, found in 22% of childhood ALL (of the pre-B-cell subtype).[347] In contrast to the translocation generating the *E2A-PBX1* fusion gene most of the *ETV6-RUNX1* fusions seem to originate in utero.[348]

Another transcription factor associated with human malignancies, *EVI1*, is specifically expressed in LT-HSCs. When overexpressed in mice *EVI1* boosts LT-HSC self-renewal, whereas its heterozygous loss leads to marked reduction of their self-renewal capacity.[349] Aberrant expression of *EVI1* isoforms is observed in 8% to 11% of AML,[350,351] and 28% of mixed-lineage leukemia (MLL)-rearranged AML,[352] and usually associated with a poor prognosis.[351] Furthermore, its translocation with *ETV6* or *RUNX1* is associated with progression to blast crisis in chronic myeloid leukemia (CML).[353,354]

The Homeobox Cluster in Hematopoietic Stem Cell Self-Renewal

Homeobox (HOX) genes encode homeodomain-containing transcription factors critical for embryonic patterning, organized into four paralogous clusters (A, B, C, and D) on four chromosomes.[355] Because of limited DNA sequence specificity and selectivity, HOX proteins function through interaction with DNA-binding cofactors, in particular, PBX and/or myeloid ectopic insertion site (MEIS) family members.[356,357] At least 22 of the 52 HOX genes (none from the HOXD cluster) are expressed in mouse and human HSPCs and are subsequently downregulated to permit lineage commitment.[358] Therefore, continuous HOX expression generally blocks differentiation and leads to rapid expansion of preleukemic HSPCs. In mice, overexpression of *HOXA10* has been shown to block myeloid and lymphoid differentiation leading to AML.[359] This is also the case for *Hoxa9*, in particular conjunction with *Meis1* or the *E2A-Pbx1* fusion gene.[360–362] *HOXA9* overexpression belongs to a gene signature that distinguishes AML from ALL, and in AML patients which highly correlates with treatment failure.[363]

A number of leukemic chromosomal translocations, either directly or indirectly, lead to the overexpression of HOX genes (see Chapter 58). The nuclear pore complex protein NUP98 was first implicated in hematologic malignancies by the discovery of *NUP98-HOXA9* fusions in AML.[364,365] Approximately half of all *NUP98* translocations involve HOX genes, most commonly *HOXA9* in AML, MDS, CML, and CMML, but also *HOXA11* and *HOXA13* as well as their paralogues in the B and C cluster.[366,367] While the overall prevalence of these fusions is low, they are associated with a poor prognosis.[368]

In normal HSPCs, the expression of HOX genes is regulated by MLL1,[369] as part of a multiprotein complex that regulates the chromatin structure at HOX clusters.[370,371] MLL1 fusion proteins in *MLL1*-rearranged leukemias further induce the transcription of specific HOX genes including *HOXA5*, *HOXA9*, and *HOXA10*.[372,373] Indeed, HOX gene overexpression is essential for MLL1-fusion induced leukemogenesis as demonstrated by the dependence of transplanted AMLs induced by both *MLL1-ENL* and *MLL1-AF4* rearrangements on *HOXA9*.[374,375]

Transcription Factor Networks

Transcription factors act within larger multiprotein complexes. In the setting of hematopoiesis, transcription factors often act positively to sustain their own expression, while simultaneously acting to cross-regulate other transcription factors, thereby establishing complex transcriptional networks. With the advent of genome-wide molecular studies, networks can be constructed computationally. Examples include a core heptad regulatory network consisting of SCL, LYL1, LMO2, ERG, FLI1, GATA2, and RUNX1 which binds to over 1000 genes in HSPCs[376,377] or a regulatory module composed of GATA1, GFI1, and GFI1B with a potentially important role in specifying early lymphoid cells.[378] Also, profiling of transcription factors in single HSPCs combined with computational lineage progression analysis suggests a role for GATA2 in driving a network that specifies megakaryocytic and erythroid from lymphomyeloid lineage cells.[379] As these constructed networks become more mature, in silico methods will predict developmental outcomes that can be tested experimentally by modulation of one or multiple transcription factors in a direct manner.[380] A comprehensive understanding of how gene regulatory networks are perturbed in hematologic malignancies may lead to new therapeutic approaches based on restoring normal regulatory patterns.

Epigenetic Regulation of Hematopoietic Stem Cell Self-Renewal

Epigenetic regulation (see Chapter 2) leads to a "stably heritable phenotype resulting from changes in a chromosome without alteration in the DNA sequence."[381] Epigenetic modifications include DNA methylation, covalent histone modification, chromatin remodeling, and mechanisms involving noncoding RNAs (ncRNAs) which will be discussed further later. By modifying chromatin structure and accessibility, epigenetic mechanisms regulate the expression of genes involved in determining the balance between self-renewal and lineage commitment of HSCs, ultimately leading to all hematopoietic cell types. Epigenetic dysregulation has been implicated in the pathogenesis of virtually all hematologic malignancies.[382,383] In contrast to genetic mutations, epigenetic alterations are in principle reversible, making epigenetic modifiers attractive targets for the treatment of hematologic malignancies. Fig. 9.2 depicts key epigenetic factors within the hematopoietic hierarchy, and Table 9.1 summarizes the main roles of critical epigenetic factors in HSPCs and hematologic malignancies.

DNA methylation plays a critical role in HSC self-renewal and commitment.[384–387] Through recruitment of multiprotein complexes, methylated DNA results in transcriptional repression of nearby genes. In mammalian cells, DNA methylation occurs at cytidines, mostly in the context of CpG dinucleotides, dispersed throughout the genome and clustered (as CpG islands) within gene promoters. In a number of hematologic cancers, for example, the progression from MDS to AML, promoter CpG islands become hypermethylated and the affected genes, including tumor suppressor genes, silenced.[388] Furthermore, subgroups of AML can be defined by unique DNA methylation profiles, which can be used to stratify AML patients with respect to their overall survival.[389] The family of DNA methyltransferases includes the de novo DNA methyltransferases DNMT3A and DNMT3B that establish methylation whereas another family member, DNMT1, maintains DNA methylation.[390,391] DNA methylation is required for HSCs to differentiate. Conditional knockout of *Dnmt3a* in mice, further pronounced by ablation of *Dnmt3b*, leads to an accumulation of self-renewing HSCs in the BM which lose their differentiation capacity upon serial transplantation.[392,393] Next-generation sequencing studies have identified *DNMT3A* mutations in most hematologic malignancies, in particular in patients with cytogenetically normal AML (over 30%),[394] where they can be detected as preleukemic lesions,[335,395] and T-ALL (16%[396]; for a complete list see[397]). In contrast, *DNMT1* mutations are rarely found in AML.[383] In agreement with the high frequency of *DNMT3A* mutations in these malignancies and the persistence of *DNMT3A*-mutant clones after chemotherapy, a recent study found that mouse HSCs depleted of *Dnmt3a* can regenerate over 12 rounds of transplantation, with the transplanted HSC pool becoming more homogenous, that is, harboring fewer somatic variants, over time.[398]

Recently it was discovered that DNA methylation is, in fact, reversible,[399,400] owing to the activity of ten-eleven translocation (TET) proteins (TET1, TET2, and TET3), which iteratively oxidize 5-methylcytosine present in methylated CpG dinucleotides.[401] Mice deficient for *Tet2*, the only TET expressed in the BM, showed enhanced HSC self-renewal and developed a CMML-like disease.[402–404] *TET2* is mutated in 49% of CMML[405] and up to 23% of AML patients (see Chapter 59 and 73).[406–408] In a mouse model of *Tet2* deficiency, vitamin C treatment mimicked *Tet2* restoration by enhancing TET function, and prevented the progression of CMML and AML.[409] Conversely, depleting vitamin C levels in mice increased self-renewal of HSCs, in part by reducing TET2 function, and vitamin C depletion cooperated with leukemic $Flt3^{ITD}$ mutations to promote leukemogenesis.[410] Interestingly, gain-of-function mutations in isocitrate dehydrogenase 1 and 2 (*IDH1/2*) that indirectly impair TET2 function are mutually exclusive with *TET2* mutations in AML (see Chapter 59). *IDH1* and *2* are found mutated in 13% to 33% of AML cases and lead to similar methylation profiles as *TET2* mutations.[411–415] IDH1/2 enzymes catalyze the conversion of isocitrate to α-ketoglutarate (α-KG), but mutated IDH1/2 converts α-KG further to 2-hydroxyglutarate, which inhibits the α-KG dependent TET2 enzyme.[416,417] In contrast, both in AML and T-cell lymphoma cases, DNMT3A and TET2 mutations have been found to co-occur,[418,419] and mutations in both genes cooperate to promote leukemogenesis in mice.[419]

The effects of histone modifications (see Chapter 2) are combinatorial in nature, and there is crosstalk between DNA methylation and histone modifications.[420] Histones have protruding flexible and charged NH_2-termini ("tails") that can be post-translationally modified in various ways, by methylation, acetylation, phosphorylation, ubiquitination, and SUMOylation, to name but a few.[421] Many histone modifications have been implicated in HSC self-renewal by knockout or overexpression of chromatin regulators that function as their "writers," "readers," or "erasers" (for a recent list, see Ref. 422). Recurrent mutations of CREBBP and/or EP300, members of the histone acetyltransferase family that activate transcription, have been detected in several lymphoma types,[423] and 18% of relapsed pediatric ALL patients see Chapters 66 and 78 exhibit mutations in the enzymatic domain of CREBBP, which are thought to contribute to drug resistance.[424]

Unlike histone acetylation, methylation of histones can have activating or repressive effects, dependent on the context and the targeted histone residue. With respect to active marks, most epigenetic studies have focused on lysine methylation carried out by lysine methyltransferases (KMTs) and removed by lysine demethylases (KDMs). The large multidomain KMT *MLL1* is essential for the generation of definitive HSCs in the mouse,[425] likely through its regulation of HOX cluster genes.[369] The *MLL1* locus has been found to be involved in chromosomal translocations in up to 70% of infant and childhood AML and ALL and in 5% to 10% of adult leukemia (see Chapter 56),[426] which is generally associated with a poor prognosis.[427] 85% of *MLL1* translocations involve six proteins (AF4, AF9, ENL, AF10, ELL, and AF6), of which MLL1-AF4 in ALL and MLL1-AF9 in AML are most common.[428] Many MLL1 fusion partners belong to the super elongation complex (SEC); when fused to MLL1 the aberrantly recruited SEC bypasses the normal transcription initiation-to-elongation checkpoints leading to high expression of MLL1-regulated genes such as HOX, WNT, and leukemic stem cell (LSC) target genes.[429] Furthermore, almost all fusion proteins aberrantly recruit another KMT, DOT1L, which by methylating H3K79 induces the expression of MLL1 target genes sufficient for leukemogenesis such as *HOXA9* and *MEIS1*.[360] In addition, MLL1 fusion proteins provoke a global loss of DNA methylation in AMLs.[430] Still, *Dnmt1* haploinsufficiency, while not perturbing normal HSC function, significantly delays leukemia progression in the *MLL-AF9* AML mouse model.[431]

At many lineage-specifying promoters in HSCs, epigenetic activators are balanced with repressive complexes, namely the polycomb repressive complex 1 (PRC1) and PRC2. The latter typically comprises the catalytically active EZH2, as well as EED and SUZ12, and is responsible for di- and trimethylation of H3K27, a repressive histone mark that is then "read" and maintained by PRC1 through histone H2A ubiquitination.[432,433] EZH2 also recruits DNA methyltransferases to its target genes, thereby enhancing its repressive effect.[434] Overexpression of *Ezh2* in mice enhances LT-HSC self-renewal by silencing differentiation genes[435,436] and causing a shift to the expression of proliferation genes.[437] EZH2 has been described with either tumor suppressive or oncogenic roles, depending on the cellular context. *EZH2* gain-of-function mutations, resulting in overall "hyper-trimethylation," occur in 7.2% and 21.7% of follicular lymphoma and diffuse large B-cell lymphoma, respectively (see Chapter 78). Loss-of-function mutations have been observed in 12% of myelodysplastic/myeloproliferative neoplasms and 18% of T-ALL cases but are rare in de novo AML (1% to 2%) (see Chapters 59, 66 and 73). PRCs do not bind to DNA directly but require the interaction with other proteins such as ASXL1. *ASXL1* is mutated in 6% to 30% of AML and 43% of CMML.[411] These mutations hinder ASXL1 from recruiting PRC2 to and thus repressing target genes such as *HOXA9*.[438]

Histone positioning or sliding, ejection and the incorporation of histone variants is achieved by ATP-dependent chromatin remodeling complexes which can be classified into four families, imitation switch (ISWI), chromodomain helicase DNA-binding (CHD), switch/sucrose non-fermentable (SWI/SNF), and INO80.[439] Multiple subtypes exist within each family, so that the composition of remodeling complexes varies across tissues and differentiation stages. Several subunits of the mammalian BAF subtype of SWI/SNF remodelers have been found to be essential for HSC function.[440,441] On the other hand, the BAF complex ATPase subunit BRG1 (SMARCA4) is required for leukemia maintenance,[442,443] in particular, by remodeling chromatin at Myc enhancers in mouse AML cells.[443]

Recurrent loss-of-function mutations in ARID1A (BAF250a) occur in acute promyelocytic leukemia,[444] and conditional *Arid1a* knockout resulted in an accumulation of LT-HSCs that, however, retained markedly reduced multilineage reconstitution capability.[445] Molecularly, Arid1a loss leads to a globally repressed chromatin landscape, including at several genes critical for hematopoietic differentiation.[445] BPTF, a member of the NURF subtype of the ISWI remodelers, has been shown to promote chromatin accessibility at genes involved in HSC "stemness" such as *Meis1*, *Pbx1*, *Mn1*, and *Lmo2*, and, indeed, maintenance of adult HSCs including LT-HSCs requires BPTF.[446]

Beyond studying the importance of epigenetic modifications, recently, attention has been directed toward higher chromatin organization in HSC function (see Chapter 4). Within nuclei, chromosomes occupy territories, and, within those, transcriptionally active euchromatin and inactive heterochromatin segregates into so-called A and B compartments, respectively. Compartments in turn are subdivided into regions called topologically associating domains (TADs), which are anchored by the CCCTC-binding zinc finger protein CTCF and the cohesin complex and harbor enhancer-promoter loops that dynamically form in a tissue-specific manner and are required to activate gene transcription.[447] The cohesin complex member *STAG2* is mutated in 5% to 20% and 2% to 12% in MDS and AML (see Chapter 59), respectively.[448–450] In mice, *Stag2*-deficient HSCs display increased self-renewal and reduced differentiation potential, leading to a myeloid dysplasia.[451] Interestingly, while STAG1 can maintain TADs in the absence of STAG2, enhancer-promoter loops at PU.1 target genes are not formed properly, leading to the block in myeloid differentiation.[451] A recent study found that in HSPCs, but not differentiated erythroid or T cells, large genomic regions with low DNA methylation and high levels of trimethylated H3K27 form chromatin loops that connect distant chromatin regions, including regions on different chromosomes.[452] The three-dimensional chromatin organization also might contribute to the differences in phenotypes and functions between fetal liver and adult HSCs because, despite TADs being largely conserved between the two HSC types, the enhancer-promoter loops forming within them were dependent on the developmental stage.[453]

The recent development of an assay to map accessible chromatin regions (see Chapter 2) including enhancers (assay for transposase-accessible chromatin using sequencing or ATAC-seq) that operates with small numbers of cells has allowed the systematic characterization of the chromatin landscape of both HSCs and leukemic clones or single cells.[454,455] Of note, the landscape of accessible and thus "open" enhancers seems to better reflect cell identity than its transcriptional profile.[455] Furthermore, ATAC-seq profiles of cells at distinct stages of AML evolution have revealed substantial regulatory heterogeneity with individual clones exhibiting mixed chromatin profiles reminiscent of multiple healthy and normally distinct hematopoietic cell states. These findings lead to the intriguing hypothesis that leukemic cells might exist as stable intermediate cell states, which differs from healthy hematopoiesis, where stable intermediate cell states have not been observed.[455] Future large-scale single-cell studies of leukemic cells will be needed to address whether stable intermediate leukemic cell states indeed exist or whether such cells just represent clonal dominance of a rare cell type.

Regulation of Hematopoietic Stem Cells by Noncoding RNAs

Sequencing the human genome revealed that less than 1.5% of the DNA encodes proteins[456] but, remarkably, subsequent analyses discovered that still 76% of the genome is transcribed into RNA.[457] Many ncRNAs are enriched in HSCs compared to hematopoietic progenitors.[458] ncRNAs other than ribosomal RNAs and transfer RNAs are arbitrarily categorized into long ncRNAs (lncRNAs) and short ncRNAs if greater than 200 or less than 200 nucleotides long, respectively. Among the short ncRNAs, microRNAs (miRNAs) are ~22-nucleotide regulatory ncRNAs that repress gene expression predominantly by binding to the 3′ untranslated region of protein-encoding mRNAs leading to their destabilization.[459] A miRNA can target large numbers of mRNAs, and a single mRNA can be regulated by multiple miRNAs.[460] HSCs depend on miRNA function for their survival as demonstrated by the finding that deletion of *Dicer* or *Ars2*, both essential factors for miRNA biogenesis, results in HSC apoptosis and BM failure.[461,462] More than 100 different miRNAs are specifically expressed during hematopoiesis, preferentially targeting and fine-tuning expression of transcription factors and their upstream activators.[463] Hematologic malignancies show characteristic changes in their miRNA expression profiles. For example, ALL samples can be classified into subtypes according to their miRNA expression patterns.[464]

Numerous miRNAs are specifically enriched in HSPCs, including miR-155,[465] miR-125a,[462] miR-125b,[466–468] miR-29a,[469] miR-126, and miR-130a.[470] Overexpression of the miRNA cluster miR-99b/let7e/125a or miR-125a alone is capable of expanding the HSC pool in mice,[71,462,466] potentially by inhibiting apoptosis of HSCs mediated by the proapoptotic gene *Bak1*, which is a miR-125a target.[462] In addition, several miRNAs have been implicated in regulating HPC differentiation, including miR-155 (lymphoid and myeloid development),[465,472] miR-223 (myeloid development),[473,474] and the miR-181/miR-150/miR-17–92 cluster (lymphoid development).[475–478] The example of miR-155 shows that, like transcription factors, some miRNAs are repurposed during hematopoietic ontogeny.[479]

Most of the miRNAs conferring a competitive advantage to the engrafted BM have been implicated in malignant transformation, and are therefore called oncomiRs.[480] Overexpression of miR-125 family members causes myeloid and lymphoid malignancies in mice[466,468,471,481,482] and they are upregulated in chromosomal translocations leading to MDS/AML and B-cell ALL.[483–485] oncomiRs contribute to leukemic phenotypes by different mechanisms such as expediting cell cycle transitions,[469] targeting tumor suppressors such as TET2,[486] or dysregulating the balance between lineage-specific transcription factors.[472] miR-155, the first miRNA shown to be sufficient to cause lymphoblastic leukemia or high-grade lymphoma in a transgenic mouse model,[487] is overexpressed in B-cell lymphomas[488] and AML.[489,490] miR-196, which is upregulated specifically during the transition from quiescent LT-HSCs to ST-HSCs, targets several of its neighboring HOX genes important for self-renewal such as *HOXA9*.[479,491–494] Like HOX genes, miR-196b is transcriptionally regulated by MLL and highly induced in MLL-rearranged leukemias, contributing to an unfavorable prognosis.[493–495] In this context, miR-196 has been shown to be necessary for *MLL-AF9* dependent immortalization of BM cells.[495] miRNAs can also function as tumor suppressors, exerting their function by targeting oncogenes. For example, the miRNA cluster miR-15a/miR16-1 is deleted or epigenetically silenced in 68% of chronic lymphoid leukemia patients (see Chapter 76),[496] resulting in the upregulation of its target oncogene *BLC2*.[497]

In contrast to miRNAs, little is known about the expression of lncRNAs in HSPCs and only a few lncRNAs have been further functionally characterized. Several recent studies have compiled lists of lncRNAs expressed in HSCs, some of which are downregulated in more differentiated progeny[387,458] and in leukemic cells.[498] Knockdown of a lncRNA specifically expressed in mouse BM LT-HSCs increased self-renewal of HSCs in vivo and abolished recruitment of the transcription factor E2A, essential for the development of multilineage HPCs,[341] to chromatin.[499] HSCs from female mice depleted for *Xist* lncRNA (responsible for X chromosome inactivation) were shown to have maturation defects and to be compromised in their repopulation capacity.[500] Furthermore, all *Xist* mutant female mice developed highly aggressive mixed myeloproliferative neoplasms/MDS.[500] With those relatively few studies the overall relevance of lncRNAs for the pathogenesis of hematopoietic diseases is not yet well understood.

HEMATOPOIETIC STEM CELL METABOLISM

In their quiescent state, HSCs mainly rely on anaerobic glycolysis rather than oxidative phosphorylation (OxPhos) to produce ATP, in contrast to progenitors that have higher OxPhos activity (see Chapter 10).[501,502] Indeed, PPARγ antagonists were shown to enhance *ex-vivo* expansion of CB HSCs by promoting glycolysis.[503] Interestingly, Wang et al. reported that deficiencies in either the M2 isoform of pyruvate kinase (PKM2) or lactate dehydrogenase A (LDHA), two enzymes responsible for the production of pyruvate and lactate during glycolysis, respectively, result in differential effects on HSC and progenitor cell function.[504] Deletion of *Ldha* inhibited normal HSC and progenitor cell function, whereas deficiency in *Pkm2* impaired progenitor cell function without affecting HSCs.[504] The authors further showed that deficiency of either *Ldha* or *Pkm2* inhibited leukemia initiation, suggesting that these metabolic enzymes may be therapeutically useful in targeting leukemia.[504]

Due to their reliance on glycolysis, HSCs were long thought to have a low mitochondrial mass, which has been traditionally assayed using dyes, such as MitoTracker Green. However, at least adult HSCs[505] express two efflux pumps (Bcrp1 and Mdr1a/b) that prevent dye accumulation in mitochondria which has led to an underestimation of mitochondrial mass in these HSCs.[506–508] In agreement, essential roles have been found for mitochondrial metabolism in HSC maintenance. Ito et al. demonstrated that the loss of peroxisome proliferator-activated receptor δ (PPAR-δ) and inhibition of mitochondrial fatty acid oxidation (FAO) induced the loss of HSC reconstitution capacity.[509] Interestingly, this PPAR-δ-FAO axis was found to serve as a "metabolic switch" which regulated HSC symmetric versus asymmetric division.[509] In a subsequent study, the same group showed that activation of the PPAR-δ-FAO axis promotes expansion of Tie2$^+$ HSCs through Pink/Parkin-mediated mitochondrial autophagy (mitophagy).[103] Similarly, when culturing LT-HSCs under differentiation-inducing conditions, treatment with the uncoupler FCCP to lower mitochondrial activity increased their self-renewal, which was accompanied by mitophagy.[510] In contrast, Ho et al. found that young, but not old HSCs clear their healthy mitochondria in a Parkin-independent manner involving the autophagy protein Atg12.[511] Further studies will be needed to reconcile these findings with the high mitochondrial mass that now has been shown for HSCs (discussed above), and also to address the functional relevance of HSCs' heterogeneity regarding their numbers of mitochondria.[506,507,512]

The mammalian target of rapamycin (mTOR) pathway regulates cellular proliferation through metabolism and plays a critical role in hematopoiesis.[513] mTOR complex 1 (mTORC1) is a key sensor of the cellular energetic state and an important stimulator of cellular anabolism (process by which the body utilizes metabolic pathways to synthesize complex molecules from smaller units), including mitochondrial biogenesis via activation of PPARγ coactivator-1α (PGC-1α).[514] While mTORC1 activation causes HSC exhaustion,[515,516] it is required cell-autonomously for HSC regeneration, [517] indicating that mTORC1 activity must be tightly regulated in HSCs. The tumor suppressor gene *Lkb1* encodes a serine/threonine kinase that activates AMP-activated protein kinase (AMPK), which leads to inhibition of mTORC1 and promotes the function of FoxO family of transcription factors.[518] Lkb1 inactivation in mice led to an immediate loss of quiescent HSCs associated with depletion of all hematopoietic subpopulations in a cell-autonomous manner, but, interestingly, through a mechanism only partially dependent on AMPK, but rather involving mitochondrial defects, depletion of ATP and alterations in lipid and nucleotide metabolism.[518–520]

The benefit from relying on glycolysis for HSCs might be a limited exposure to reactive oxygen species (ROS) produced by several complexes of the electron transport chain responsible for OxPhos. Indeed, numbers and LT repopulating potential of HSCs are rapidly declining upon their exposure to ambient air.[521] The microenvironment in which HSCs reside has been found to be hypoxic, especially in deeper peri-sinusoidal regions.[522] In support of these results, long term HSCs express high levels of HIF-1α,[523] which is known to transcriptionally induce glycolysis.[524] However, a recent study using a newly generated dual genetic reporter line that enables better enrichment of LT-HSCs and imaging them in their native niche did not find these LT-HSCs in the BM niches with the highest level of hypoxia but rather in regions of similar oxygen tension as MPPs.[525] Thus, hypoxia does not seem to be sufficient to instruct LT-HSC potential. These observations are in agreement with other studies that suggest that glycolysis in HSCs might in fact not be driven by the induction of the HIF pathway in response to hypoxia.[526]

In addition to glycolysis and FAO, other metabolic pathways including glutamine metabolism[527] and branched-chain amino acid catabolism[528] have recently been shown to be important for HSC activation and LSC function, respectively. Furthermore, Taka et al. reported that depriving recipient mice of the essential amino acid valine depleted their BM of HSCs such that a 2-week course of a valine-free diet and subsequent transplantation of healthy donor HSCs into these recipient mice resulted in LT donor chimerism in almost all mice without the need for irradiation conditioning.[529] Even though the achieved repopulation levels by donor HSCs was still low, these results suggest that valine starvation could be further explored as a strategy to replace myeloablative conditioning.

The therapeutic importance of understanding the cellular metabolic state of HSCs was recently highlighted by Liu et al.,[530] who showed that treatment of HSCs with alexidine dihydrochloride, a selective inhibitor of the mitochondrial phosphatase PTPMT1, reprogrammed HSC metabolism from mitochondrial respiration to glycolysis, increasing HSC maintenance in culture. Alterations in HSC metabolism have also been reported to impact HSC function with aging. Mohrin et al. reported that SIRT7, a histone deacetylase which regulates the expression of the mitochondrial master regulator, nuclear respiratory factor 1, is reduced in aged HSCs.[531] SIRT7 loss of function led to increased mitochondrial protein folding stress (PFS^{mt}) that was accompanied by an induction of the mitochondrial unfolded protein response (UPR^{mt}), and a compromised regenerative capacity of HSCs.[531] Intriguingly, reintroduction of SIRT7 into aged HSCs reduced the PFS^{mt} and multilineage reconstitution capacity of aged HSCs,[531] indicating that dysregulated cell-intrinsic protective programs such as the UPR^{mt} might be targetable to reverse HSC aging. Improved methods that allow the accurate metabolic profiling of small numbers of sorted HSCs will be instrumental in better understanding HSC function.[532]

TABLE 9.2 **Soluble Proteins and Small Molecules Suggested to Regulate Hematopoietic Stem Cell Self-Renewal or Expansion**

Growth Factor	Function in HSC Self-Renewal	Reference[a]
NOTCH ligands	Sufficient, not necessary	216, 220–222, 226, 227
WNT proteins	Sufficient, ? necessary	234, 238, 250, 252
BMPs	? Sufficient, *SMAD4* necessary	269
SCF	Necessary, not sufficient	533
TPO	Necessary, not sufficient	534
CXCL12	Necessary	288, 291
RAR-γ	Necessary	153
ANGPTL	Sufficient	535, 536
PGE_2	Sufficient	539, 542
PTN	Necessary, sufficient	143, 548
AHR antagonist	Sufficient	550
UM171	Sufficient	556
PPAR-γ antagonist	Sufficient	570
Zwitterionic Hydrogel	Sufficient	574
Polyvinyl alcohol	Sufficient	565
Valproic acid	Sufficient	569
Nicotinamide	Sufficient	564

[a] References are representative, not all-inclusive.

AHR, Aryl hydrocarbon receptor; *ANGPTL*, angiopoietin-like protein; *BMP*, bone morphogenetic protein; *CXCL12*, C-X-C motif chemokine 12; *HSC*, hematopoietic stem cell; *PGE_2*, prostaglandin E_2; *PTN*, pleiotrophin; *RAR-γ*, retinoic acid receptor γ; *SCF*, stem cell factor; *TPO*, thrombopoietin.

NOVEL GROWTH FACTORS FOR EXPANDING HEMATOPOIETIC STEM CELLS AND CLINICAL TESTING

Several novel proteins and small molecules have been reported to promote potent expansion of murine or human HSCs in culture (Table 9.2).[143,533,534] Moreover, leveraging insights into the mechanisms which regulate HSC self-renewal and differentiation, several different approaches to expand human CB HSCs have been tested in early clinical trials. Zhang et al.[535] reported the discovery of the proteins angiopoietin-like 2 (ANGPTL2) and ANGPTL3 in a fetal liver stromal cell line and demonstrated that the addition of ANGPTL2 or ANGPTL3 to cytokine cultures supported a 24- to 30-fold expansion of human BM cells capable of LT repopulation in NOD/SCID mice. Subsequently, Zhang et al.[536] demonstrated that the addition of ANGPTL5 and insulin-like growth factor binding protein 2 (IGFBP2) to the combination of SCF, TPO, and FGF1 supported up to a 20-fold increase in human CB cells capable of 8-week engraftment in NOD/SCID mice. Of note, because the addition of ANGPTL5 and IGFBP2 did not substantially increase total cell expansion compared with SCF, TPO, and FGF1 alone, it remains possible that treatment with ANGPTL proteins or IGFBP2 may enhance the homing of HSCs in immune-deficient transplant models.[536] Because of their potency in expanding human CB HSCs in preclinical models, ANGPTL proteins represent attractive targets for translation into the clinic. Several ANGPTL proteins, including ANGPTL2 and ANGPTL5, have been found to bind and activate the immune-inhibitory receptor human leukocyte immunoglobulin–like receptor B2 (LILRB2).[537] Interestingly, studies in zebrafish and human cells indicate that ANGPTL2, through its interaction with LILRB2, leads to cleavage and activation of the NOTCH receptor, ultimately inducing MYC target genes stimulating HSPC formation and expansion.[538]

North et al.[539] reported that prostaglandin E_2 (PGE_2) positively regulates HSC formation in the zebrafish model. These authors also demonstrated that ST (2-hour) treatment of murine HSCs with PGE_2 produced a two- to threefold increase in donor cell repopulation in transplanted mice compared with mice transplanted with untreated cells.[539] Subsequently, Goessling et al.[540] showed that PGE_2 modulates WNT signaling via regulation of β-catenin degradation and PGE_2/WNT activation regulated both hematopoietic regeneration in the zebrafish and LT HSC repopulation in mice. Hoggatt et al.[541] also showed that ST exposure to PGE_2 promoted the enhanced homing and repopulation of human CB HSCs in immune-deficient mice caused by increased CXCR4 expression on PGE_2-treated CB HSCs. Ex vivo treatment with PGE_2 was subsequently shown to increase human CB CFC content and engraftment capacity after transplant into immune-deficient mice, and PGE_2-treated BM cells were also found to provide more than one year of multilineage reconstitution in a nonhuman primate model.[542] Based on these encouraging results, a phase I clinical trial was undertaken, in which one unmanipulated CB unit and a second CB unit that was cultured for two hours in the presence of 16,16-dimethyl PGE_2 ($dmPGE_2$) were transplanted into adult patients after nonmyeloablative conditioning. $dmPGE_2$-treated CB cells resulted in accelerated neutrophil recovery (17.5 days vs. 21 days) and LT engraftment in 10 of 12 patients.[543]

Recently, screening strategies in human cells have been successfully used to identify novel growth factors, developmental factors, and chemical compounds for HSCs. Himburg et al. identified pleiotrophin (PTN), a heparin binding growth factor, from a gene expression analysis of human brain-derived ECs that support human HSC expansion in vitro.[544–547] Treatment of murine BM HSCs with PTN produced a 10-fold expansion of LT repopulating HSCs in culture, and systemic administration of PTN to irradiated mice caused a 20-fold increase in the recovery of BM LTC-ICs in vivo.[143] Mechanistically, PTN signaling caused the upregulation of PI3K/AKT signaling and *Hes1* expression in HSCs, suggesting that activation of these signaling cascades may contribute to PTN-mediated HSC expansion.[143] Mice lacking *Ptn* had 11-fold less BM HSC content than their wild-type littermates.[548] Interestingly, LT-HSC content, as measured in tertiary and quaternary transplants, was increased in chimeric mice with *Ptn* deletion in the BM microenvironment compared with wild-type mice.[549] Taken together, these results suggest that PTN regulates BM HSC expansion and regeneration, and in the context of constitutive *Ptn* knockout, *Ptn* loss in hematopoietic cells may dominate over effects of *Ptn* loss in the niche.[549] Further studies utilizing Cre-loxP technology to delete PTN specifically in VEcadherin+ BM ECs and lepR+ stromal cells revealed that PTN produced by lepR+ stromal cells is important for HSC maintenance in vivo, whereas HSC regeneration following total-body irradiation (TBI) is differentially dependent on PTN production by BM ECs.[550]

Boitano et al.[551] described a screening approach of more than 100,000 heterocyclic compounds for the capacity to maintain human $CD34^+$ cells in culture for five days. This screen yielded the discovery of the purine derivative StemRegenin 1 (SR1), which was shown to promote the expansion of human CB repopulating cells in vitro.[551] Three-week cultures of human CB $CD34^+$ cells with thrombopoietin, SCF, FLT3 ligand, interleukin-6 (IL-6), and SR1 promoted a 17-fold increase in SCID-repopulating cells compared with the progeny of cultures containing thrombopoietin, SCF, FLT3 ligand, and IL-6 alone.[551] SR1 appears to mediate its effects via inhibition of the aryl hydrocarbon receptor. Aryl hydrocarbon receptors are expressed by HSCs, but the downstream signaling mechanism through which SR1 mediates HSC expansion remains unknown.[551] Dahlberg et al. reported that the combination of SR1 with the NOTCH ligand, $Delta^{Ext\text{-}IgG}$, caused a threefold increase in human CB-derived myeloid repopulation in NSG mice at two weeks compared to CB cells cultured with $Delta^{Ext\text{-}IgG}$ or SR1 alone.[552] Results from a phase I trial of transplantation with SR1-treated CB cells have demonstrated the feasibility and safety of this approach.[553]

In a recent analysis of growth factors elaborated by an AGM-derived stromal cell line, Wohrer et al. reported that nerve growth factor and collagen 1, when added to a defined serum-free medium containing SCF and IL-11, produced fourfold expansion of murine LT repopulating HSCs in seven-day cultures compared to SCF and IL-11 alone.[554,555] Separately, treatment of human CB HSCs with a pyrimidoindole derivative, UM171, was shown to promote a 13-fold expansion of CB cells capable of repopulating NSG mice at 20 weeks posttransplantation.[556] Although the mechanism of action of UM171 has not been elucidated, preliminary analyses suggested that UM171 inhibited erythroid and megakaryocytic differentiation of human HSCs in culture. Jaroscak et al.[557] tested the combination of FLT3 ligand, a GM-CSF/IL-3 fusion protein, and erythropoietin in a continuous perfusion culture system as a means to expand human CB cells before transplant. Similarly, Shpall et al.[558] tested the capacity of SCF, granulocyte colony-stimulating factor (G-CSF), and megakaryocyte growth and differentiation factor to expand human CB cells that were then transplanted into adult CB transplant recipients. An alternative approach to cytokine-based expansion of human CB cells was suggested by Peled et al.,[559–561] who demonstrated a 159-fold increase in human $CD34^+$ cells after seven-week culture with a copper chelator, tetraethylenepentamine (TEPA), and cytokines. Subsequently, de Lima et al.[562] reported the safety and feasibility of culturing human CB cells with TEPA and SCF, FLT3 ligand, IL-6, and thrombopoietin followed by transplantation into patients in a phase I/II clinical trial. Although each of these clinical trials has shown the feasibility of transplanting ex vivo–cultured CB cells, none demonstrated substantial acceleration in hematopoietic cell engraftment in CB transplant recipients compared to historical controls.

Several other clinical trials have recently indicated progress toward the clinical expansion of human CB HSCs for therapeutic purposes. De Lima et al. reported a median time to neutrophil engraftment of 15 days in recipients of one unmanipulated CB unit plus CB cells cultured with mesenchymal stromal cells, compared to 24 days in historical controls, although LT donor hematopoiesis derived almost exclusively from the unmanipulated CB unit.[563] Lastly, Horwitz et al. reported that transplantation of one unmanipulated CB unit and the progeny of 21-day culture of human CB cells with nicotinamide produced earlier neutrophil recovery (13 versus 25 days for historical controls) and dominant engraftment from the nicotinamide-treated CB unit in eight of 11 treated patients.[564] The approach with nicotinamide to expand human HSCs for use as grafts for allogeneic transplantation has proceeded along the pathway to possible clinical approval. When administered to a transplant recipient in phase II clinical trial a CB singled unit expanded ex vivo with nicotinamide shortened the median time to neutrophil recovery by 9.5 days (95% CI, 7 to 12 days) and median platelet recovery by 12 days (95% CI, 3 to 16.5 days), establishing the feasibility, safety, and efficacy of an ex vivo expanded UCB unit as a stand-alone graft. The efficacy of nicotinamide expanded CB stem cells has been further evaluated in an open-label controlled, multicenter, international, Phase III, randomized study comparing the reconstitution kinetics following transplantation of a single CB unit expanded with nicotinamide versus transplantation of one or two un-manipulated, unrelated CB units in patients with ALL AML, MDS, CML, or lymphoma, with required disease features rendering them eligible for allogeneic stem cell transplantation. The final results of this trial are eagerly awaited. At the more basic level, recent studies have shown that treatment with Nicotinamide riboside attenuates age-associated loss of hematopoietic stem cell function in mice, suggesting additional therapeutic potential for this approach.[565]

In addition to these approaches that are being tested in clinical trials of human CB expansion, several novel mechanisms have been identified that may provide the basis for additional clinical trials of the products of ex vivo human HSC expansion. Wilkinson et al.[566] reported culture methods including polyvinyl alcohol as a replacement for albumin, coupled with high concentrations of thrombopoietin, that produced between 236-fold and 899-fold expansion of murine HSCs capable of in vivo repopulation over 1 month. Several additional methods have recently been described to expand human CB HSCs, including by Shao et al.,[567] who demonstrated that HSCs express the neurotransmitter receptor Gabbr1, and that treatment of human CB HSPCs with a GABBR1 agonist caused the expansion of cells capable of engraftment in immune-deficient mice. Similarly, Hua et al.[568] reported that treatment of human CB HSCs with a bromodomain and extra-terminal motif inhibitor, CP1203, caused the expansion of CB cells capable of long-term engraftment in-immune deficient mice. Interestingly, inhibition of the epigenetic regular lysine-specific histone demethylase 1A (LSD1) promotes the expansion of CB CD34+ cells in culture and long-term CB HSCs via blockade of differentiation.[569] The authors also showed that LSD1 is a mechanistic target of UM171, which expands human CB HSCs and is currently being evaluated in clinical trials. Separately, Zimran et al. demonstrated that treatment of human CB CD34+ cells or adult human BM or mobilized peripheral blood CD34+ with the histone deacetylase inhibitor, valproic acid, produced a significant expansion of human cells capable of engraftment in immune deficient mice.[570] Treatment of human CB HSCs with a peroxisome proliferator–activated receptor (PPAR)-γ antagonist, GW9662, was also shown to significantly increase cytokine-mediated expansion of CB HSCs with repopulating capacity.[571] These authors further showed that treatment with the PPAR-γ antagonist promoted CB HSC expansion via enhancement of HSC glycolysis, suggesting that the metabolic state of human HSCs directly impacts in vivo repopulating capacity. Other candidate mechanisms that have been described to expand human HSCs include treatment with a recombinant form of the DNA-binding chromatin factor, DEK, which acts via CXCR2 and heparan sulfate proteoglycans on HSCs,[572] and Nov (CCN3), a matricellular regulator, that was shown to increase the frequency of human CB HSCs with serial repopulating capacity after only 8 hours of incubation.[573] Remarkably, Nov incubation increases HSC repopulating capacity and clonogenicity without increasing HSC numbers through cell division, suggesting that Nov incubation harnesses latent stem cell activity in CB HSCs.[573] Calvanese et al.[574] performed a transcriptomic analysis of self-renewing human fetal liver HSCs versus cultured HSPCs to identify the transcription factor MLLT3 as a candidate regulator of human HSC self-renewal. These authors showed that forced expression of MLLT3 in human HSCs promoted greater than 12-fold expansion of human HSCs capable of engrafting NSG mice and sustained levels of H3K79me2, while maintaining the HSC transcriptional program in culture.[574] Bai et al.[575] demonstrated an expansion of human CB cells capable of long-term reconstitution in immune-deficient mice using a zwitterionic hydrogel 3D culture system. Mechanistically, the authors showed that this novel culture system promoted HSC self-renewal due to inhibition of ROS generation in culture. Finally, the translational potential of methods to expand human HSCs was validated recently by the successful completion of a clinical trial of autologous ex vivo lentiviral gene therapy for patients with adenosine deaminase deficiency.[576] In this study, the authors cultured human BM CD34+ cells with SCF, flt-3 ligand, thrombopoietin, and IL-3 for 40 hours to facilitate lentiviral integration and showed LT normalization of ADA activity in transplanted patients. Taken together, these studies suggest that the greater understanding of mechanisms that regulate human HSC self-renewal and methods to sustain human HSCs in culture will continue to increase, raising hope for the realization of a translatable, reproducible method to expand human HSCs for therapeutic purposes, including gene therapy.

GENERATING HEMATOPOIETIC STEM CELLS FROM PLURIPOTENT STEM CELLS AND BY REPROGRAMMING OF SOMATIC CELLS

Globally more than 50,000 patients per year receive allogeneic and autologous HSC transplantations as treatments for congenital and acquired hematopoietic diseases and other malignancies.[577] At present, the only cell sources for HSC transplantations are BM, CB, or mobilized peripheral blood. However, insufficient numbers, shelf-life concerns as well as immunologic incompatibility leading to graft-versus-host disease, even in human leukocyte antigen–matched grafts, limits their availability.[577,578] One option to generate more HSCs is by expanding existing HSCs in vitro as described earlier. Despite substantial efforts, this has proven difficult; because of the tendency of HSCs to differentiate in culture, the expansion of HSCs is not very efficient and does not lead often to fully functional HSCs in terms of their migratory behavior and LT multilineage reconstitution potential.[579,580]

The observation in 1981 that embryonic stem cells (ESCs) could be derived from mouse or, later, human blastocysts[581–583] fueled efforts to differentiate HSCs from ESCs. In 2006, the discovery that mouse or human fibroblasts could be reprogrammed to induced pluripotent stem cells (iPSCs) by retroviral transduction with the same four factors, OCT3/4, SOX2, KLF4, and c-Myc,[584,585] opened the door to the possibility of autologous stem cell–based therapies in the clinic.[586,587] Since its first report, this technology has been constantly modified[588] and is allowing the generation of iPSC lines from patients with a variety of blood disorders (references in 589). This approach presents a new opportunity for disease modeling and drug screening.

Numerous methods for directed differentiation of HSCs from ESCs or more recently iPSCs have been developed, but so far none yield long-lived cells with full HSC functionality. In one study, inducible expression of five transcription factors, *HOXA9*, *RORA*, *ERG*, *SOX4*, and *MYB*, imparted human ESC- and iPSC-derived progenitors with ST myeloid and erythroid engraftment potential.[589] This and similar approaches are characterized by the lack of robust lymphoid potential, likely because these progenitors are developmentally still too immature.[590]

In light of the obstacles in generating HSCs from ESCs or iPSCs, approaches to directly reprogram somatic cells into HSCs, or transdifferentiate them to hematopoietic cells are being explored as alternative strategies. The concept of direct reprogramming was first demonstrated with the conversion of embryonic fibroblasts into contracting myocytes by just the transcription factor MyoD.[591] Pluripotency-related factors are upregulated during endogenous reconstitution of mouse hematopoiesis after irradiation.[592] Thus, studies successfully reprogramming human skin fibroblasts directly into HSPC-like cells used the pluripotency factors OCT4 or SOX2 together with a specific cytokine cocktail.[592,593] While these cells engrafted, they again lacked lymphoid potential. In contrast to these examples of indirect lineage conversion via a less differentiated state, direct lineage conversion (or transdifferentiation) attempts have included the enforced expression of transcription factors critical for normal hematopoiesis.[594] In analogy to the HSC-producing hemogenic endothelium, human umbilical vein ECs cultured on an artificial vascular niche and overexpressing four transcription factors (*FOSB*, *GFI1*, *RUNX1*, and *PU.1*) yielded serially transplantable hematopoietic colonies.[595] However, these cells did not differentiate into T cells. In another approach demonstrating the benefit of the niche, lymphoid or myeloid progenitors were transduced with a transcription factor cocktail (*HLF*, *LMO2*, *PBX1*, *PRDM5*, *RUNX1T1*, and *ZFP37*) and matured in irradiated mice to yield serially transplantable HSCs producing all lineages.[596] Despite this progress in mice, fully functional human HSCs have not yet been generated in vitro using this technology. In addition, future studies will have to focus on strategies to avoid the risk of malignant transformation inherent in any directed differentiation or cellular reprogramming method.[597]

HEMATOPOIETIC STEM CELL REGENERATION

Although much is now known about the intrinsic and extrinsic mechanisms that regulate adult HSC self-renewal and differentiation,[1,215,237] the process through which HSCs regenerate after injury (e.g., chemotherapy or radiation) remains less well understood. Successful delineation of the mechanisms that control HSC regeneration could have significant therapeutic implications because a large proportion of cancer patients receive myelosuppressive or myeloablative therapy during the course of their disease. Signaling through the BMP and WNT signaling pathways has been shown to be necessary for hematopoietic regeneration to occur in zebrafish after sublethal irradiation.[598] These authors further demonstrated that SMAD and TCF, the downstream effectors of BMP and WNT signaling, respectively, couple with master regulators of myeloid and erythroid differentiation (C/EBPα and GATA1) to drive lineage-specific regeneration.[598] In a murine model of hematopoietic injury, Congdon et al.[599] showed that *Wnt10b* expression is increased in BM stromal cells in response to irradiation, and WNT signaling is activated in BM HSCs after irradiation. As discussed earlier, in a zebrafish model, activation of WNT signaling during hematopoietic regeneration is modulated by PGE_2.[540] WNT reporter activity was responsive to PGE_2 treatment, and the effect of Wnt8 toward enhancing hematopoietic recovery after sublethal irradiation was inhibited by administration of indomethacin, a PGE_2 antagonist.[540] NOTCH signaling has also been implicated in the regulation of hematopoietic regeneration after stem cell transplantation.[328] Deletion of *Notch2*, but not *Notch1*, was shown to delay myeloid reconstitution in mice after stem cell transplantation.[219] These data suggest that the BMP, WNT, and NOTCH pathways are attractive mechanistic targets for strategies to augment hematopoietic regeneration after myelosuppressive therapy.

Additional signaling pathways have been implicated in regulating hematopoietic regeneration. Deletion of plasminogen (*Plg*), a fibrinolytic factor, was shown to prevent HPC proliferation and recovery after 5-fluorouracil (5-FU)-induced myelosuppression in mice.[600] Conversely, activation of PLG by administration of tissue *Plg* activator promoted HPC proliferation and differentiation after myelosuppression, and this effect was dependent on matrix metallopeptidase 9–mediated release of c-Kit ligand.[600] Similarly, Trowbridge et al.[281] reported that mice that were heterozygous for the hedgehog receptor *Ptc1* displayed earlier recovery of hematopoiesis after 5-FU-induced myelosuppression compared with wild-type littermate mice. Hedgehog binding blocks PTC1-mediated inhibition of SMO, thereby promoting downstream Hedgehog signaling. Therefore, heterozygous *Ptc1* mice have enhanced Hedgehog signaling, and these results implicate Hedgehog signaling as positively regulating ST hematopoietic regeneration after injury. However, this acceleration in hematopoietic recovery in mice heterozygous for *Ptc1* occurred at the expense of LT-HSCs, which were exhausted in these mice.[281] Genetic studies have similarly demonstrated that the homozygous deletion of *Ship* in mice (SH2-containing inositol phosphatase) is associated with increased loss of HSCs after 5-FU exposure compared with heterozygous *Ship* deletion.[601] In a similar model of 5-FU-mediated myelosuppression, Nemeth et al.[602] reported that mice deficient in the high-mobility group box 3 (*Hmg3b*) DNA binding protein exhibited more rapid recovery of phenotypic HSCs compared with wild-type mice. The enhanced recovery of the stem/progenitor pool in *Hmgb3*-deficient mice was associated with activation of WNT signaling, again suggesting that activation of the WNT pathway may accelerate HSC recovery after myelosuppression. Of note, expression of a constitutively active form of the signal transducer and activator of transcription 3 (*Stat3*) in HSCs increases their regenerative capacity after transplant into lethally irradiated mice.[603] In this study, it was not determined whether alteration in *Stat3* expression affected HSC regeneration after myelosuppression (e.g., 5-FU or irradiation).[603]

At the cellular level, increasing evidence suggests an important role for BM ECs in promoting hematopoietic regeneration after myelotoxic stress.[604–606] Genetic deletion or antibody-based inhibition of VEGFR2, which is expressed by sinusoidal BM ECs, was shown to delay both BM vascular and hematopoietic recovery after TBI.[605] Systemic infusion of syngeneic or allogeneic ECs has also been shown to significantly accelerate the recovery of both the HSC pool and overall hematopoiesis in mice after high-dose TBI.[607,608] Salter et al.[609] and Butler et al.[225] further demonstrated that hematopoietic regeneration after irradiation is dependent on VE-cadherin-mediated vascular reorganization because administration of a neutralizing anti-VE-cadherin antibody caused significant delay in hematologic recovery in mice after TBI. While the precise mechanisms through which BM ECs regulate HSC regeneration in vivo remain unclear, it was shown that systemic administration of PTN, a heparin binding growth factor that is secreted by both BM and brain ECs, causes a rapid increase in recovery of the HSC pool in mice after high-dose TBI.[143] Taken together, these studies suggested that the BM vascular niche may be an important reservoir for the discovery of growth factors and membrane-bound proteins that mediate HSC regeneration. Additional studies have further validated the important role of the BM vascular niche in regulating HSC regeneration following myelosuppressive injury. Deletion of the proapoptotic proteins, BAK and BAX, from *Tie2*-expressing BM ECs was shown to protect HSCs from radiation-induced depletion in mice, independent of HSC-autonomous effects.[609] Furthermore, Doan et al. reported that epidermal growth factor (EGF) is expressed by BM ECs after TBI and that systemic administration of EGF improved HSC regeneration and survival after TBI.[609] EC-specific deletion of the NOTCH ligand, Jagged1, has also been shown to cause delayed white blood cell recovery and decreased survival in mice following sublethal TBI.[610] Additional studies have suggested several novel mechanisms through which HSC regeneration can be augmented following radiation-induced myelotoxicity, including augmentation of the thrombomodulin-activated protein C pathway,[611] administration of the bactericidal/permeability-increasing protein ($rBPI_{21}$),[612] activation of nuclear factor erythroid-2-related factor 2,[613] or Ras/MEK/ERK signaling in HSCs.[614] Interestingly, it has also been shown that both HSCs and leptin receptor-expressing BM stromal cells secrete ANGPT1 and that deletion of *Angpt1* in these cell populations accelerated vascular and hematopoietic recovery in mice after irradiation.[615] Furthermore Vannini and coworkers reported that nicotinamide riboside reduced mitochondrial activity within HSCs by increasing mitochondrial clearance, leading to increased asymmetric HSC divisions.[616] They reported that dietary supplementation of mice after they received lethal doses of irradiation with nicotinamide riboside resulted in a larger pool of HPC, without HSC exhaustion, improving survival by 80% and accelerating blood cell recovery. This report established a link between HSC mitochondrial stress, mitophagy, and stem-cell fate decision, and unveiled the potential for the use of nicotinamide riboside to accelerate the recovery of patients suffering from cytopenias following chemotherapy and radiation therapy. Taken together, these studies reveal the remarkable complexity and orchestration of molecular responses to myelotoxicity and also suggest several potential pathways that can potentially be exploited for the therapeutic regeneration of HSCs.

Several additional mechanisms have been discovered through which distinct components of the BM microenvironment regulate HSC regeneration. Using single cell gene expression analysis of mesenchymal osteolineage cells, Silberstein et al.[617] identified a secreted RNase, Angiogenin, as a candidate HSPC growth factor. Angiogenin was subsequently shown to decrease the proliferation of HSPCs, provide radioprotection to irradiated mice, and augment hematopoietic reconstitution of mouse and human HSPCs following transplantation.[618] Subtractive gene expression analysis of BM osterix+ mesenchymal osteoprogenitor cells in mice prior to and following TBI revealed increased expression of the Wnt antagonist, Dickkopf 1 (Dkk1), by BM osterix+ cells following irradiation. Himburg et al. showed that Dkk1 promoted early HSC regeneration in mice following TBI via direct suppression of ROS generation and HSC senescence, and indirectly via action on BM ECs, causing BM EC secretion of EGF.[619] Importantly, Zhou et al.[620] demonstrated that BM adipocytes secrete SCF in mice following TBI and adipocyte-derived SCF is essential for HSC regeneration and mouse survival following TBI. Adrenergic nerve function in the BM is also important for hematopoietic regeneration in mice following chemotherapy,[621] and adrenergic nerves regulate hematopoietic regeneration via stabilization of the BM mesenchymal stromal cell niche. Utilizing techniques to isolate sinusoidal BM ECs from arterial BM ECs, Xu et al.[622] suggested that arterial BM ECs are the primary source of EC–SCF that contributes to HSC maintenance and recovery following injury. Chen et al.[623] described a rare population of BM apelin+ ECs that critically contribute to BM vascular regeneration following myelosuppressive injury. Apelin+ BM ECs were shown to be essential for hematopoietic regeneration following BM transplantation. Separately, Himburg et al.[550] and Guo et al.[624] illustrated that EC-derived PTN and EC-derived Jagged 2 have essential roles in promoting hematopoietic regeneration following myelosuppression.

Interestingly, donor-derived granulocytes have been shown to promote recipient BM vascular regeneration and hematopoietic recovery following myeloablation in mice and this granulocyte-mediated BM vascular regeneration occurs via TNFα secretion by donor granulocytes, acting on TNFR1 expressed on recipient BM ECs.[625] In keeping with the concept of donor hematopoietic cell contribution to BM restoration following myeloablation, Golan et al.[626] showed that donor HSPCs transfer healthy mitochondria to damaged recipient BM stromal cells in manner dependent upon transfer through HSPC Connexin-43 channels. Global strategies to augment host BM stromal cell function following myelosuppressive injury have potential applications since Severe et al.[627] demonstrated that many BM stromal cell subsets are ablated by TBI.

Other novel molecules reported to regulate hematopoietic regeneration include luteinizing hormone (LH).[628] Velardi et al. demonstrated that administration of an LH-releasing hormone (LHRH) antagonist promoted HSC regeneration and survival in irradiated mice.[628] The authors showed that LH inhibition promoted HSC quiescence after injury, thereby preventing HSC exhaustion. Fang et al. reported that EGF promotes HSC regeneration in irradiated mice via augmentation of NHEJ repair in HSCs,[629] while Zhang et al.[128] demonstrated that small molecule allosteric inhibitors of the receptor PTPσ potently drove murine HSC regeneration in vivo and human HSC regeneration ex vivo. Yamashita et al.[630] demonstrated that TNFα promotes HSC survival and primes HSCs for myeloid differentiation following inflammatory stress, while simultaneously inducing myeloid progenitor cell apoptosis. Most recently, Sudo et al. reported that group 2 innate lymphoid cells promote hematopoietic regeneration following 5FU chemotherapy through secretion of GM-CSF.[631] At the molecular level, Yi et al. demonstrated an essential role for S-nitrosoglutathione reductase in controlling protein aggregation and unfolded protein response to allow HSC regeneration following 5FU chemotherapy.[632] Similarly, it has been shown that the E3 ubiquitin ligase, HectD1, has an essential role in supporting HSC regeneration by regulating ribosome assembly and proper protein translation.[633] Chavez et al. also reported that LT-HSCs upregulate expression of the transcription factor, PU.1, which represses cell cycle entry and protein synthesis to maintain the homeostatic HSC pool during stress.[634] Importantly, Kaufmann et al. recently discovered a latent subset of human HSCs that display resistance to regeneration-mediated stress.[635] Taken together, these studies provide new avenues for additional exploration of stress-resistant HSC populations and new understanding of the intrinsic and extrinsic machinery that regulates HSC survival and regeneration following injury.

Lastly, the effect of age on the capacity for HSCs to regenerate after a myelosuppressive challenge remains an important question.[636] Clinical studies have confirmed the impaired reconstitutive capacity of HSCs from older patients in autologous stem cell transplant settings.[637] Not surprisingly, older mice with defects in DNA damage repair mechanisms (nucleotide excision repair, nonhomologous end-joining) and telomere maintenance displayed severe defects in their capacity to reconstitute hematopoiesis after transplantation into lethally irradiated recipient mice compared with age-matched control subjects that retained the DNA repair and telomerase genes.[638] Furthermore, Flach et al. showed that aging HSCs display heightened levels of replication stress while cycling as a result of decreased expression of mini-chromosome maintenance replicative helicase components and altered DNA replication forks.[639] Therefore, therapeutic targeting to accentuate these DNA repair and replication mechanisms may facilitate the recovery of the functional HSC pool after myelosuppression and may lessen the oncogenic risk incurred via repeated exposure to DNA-damaging therapies (e.g., alkylators and irradiation).[631,638] Interestingly, prolonged fasting has been shown to ameliorate chemotherapy-induced HSC damage and age-dependent myeloid bias in mice, associated with reduction in IGF1 levels.[640] In keeping with these findings, long-term dietary restriction has subsequently been shown to improve hematopoietic reconstitution capacity of aged BM HSCs.[641] Further research into the HSC-autonomous and extrinsic mechanisms which regulate HSC aging and HSC regeneration during aging should be prioritized going forward and will hopefully yield therapeutic avenues to reverse some aspects of hematopoietic aging.

HEMATOPOIETIC STEM CELLS AND MALIGNANCY (SEE CHAPTERS 13 AND 59)

Similar to the HSC at the apex of the hematopoietic hierarchy, an entity termed a LSC has been proposed to drive tumorigenesis because of its ability to self-renew and reinitiate leukemia upon transplantation in an experimental setting (e.g., mouse transplant; Fig. 9.4).[642–644] A clonal origin of a hematopoietic malignancy was first demonstrated for CML where the presence of the characteristic Philadelphia chromosome in myeloid, erythroid, megakaryocytic, and B-lymphoid cells suggested a common origin,[645–647] which was later proven by molecular analyses.[648] Genetic analyses in a case of CML also provided the first proof for another important concept in cancer, that of clonal evolution (see Fig. 9.4),[649] which had already been hypothesized for solid tumors.[643] This model posits that a subclone within the initial LSC-derived clone acquires additional genetic or epigenetic alterations that convey a growth advantage and lead to heterogeneity within the tumor.[642] Whereas the HSC pool itself does not expand during progression of chronic phase CML to blast crisis, granulocyte-macrophage progenitors (GMPs) with increased expression of the continuously active tyrosine kinase fusion protein BCR-ABL and increased self-renewal capacity driven by activation of nuclear β-catenin are amplified.[650] Thus, the LSC may differ from the tumor-initiating "cell of origin."[203,650] While in CML the tumor-initiating HSC maintains the chronic phase of the disease, subsequent genetic events arising in the GMPs give rise to LSCs sustaining the blast crisis.

The first cancer stem cell to be identified was the LSC in AML.[644,651] $CD34^+CD38^-$ cells but not $CD34^+CD38^+$ cells derived from all known AML subtypes (except for the AML subtype M3)

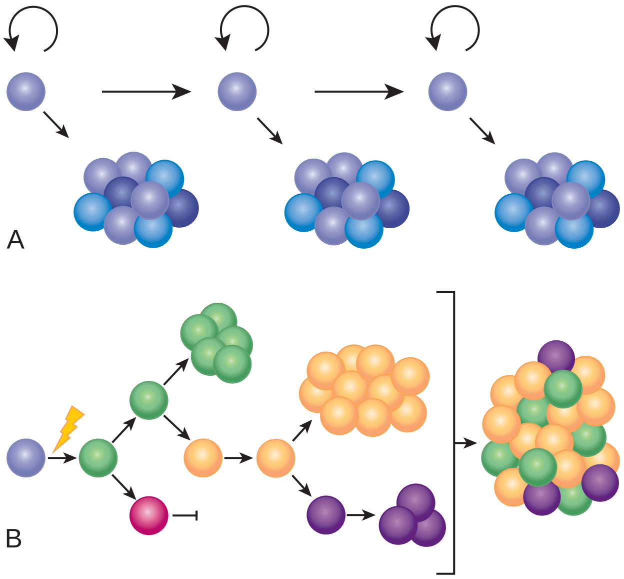

Figure 9.4 CLONAL DYNAMICS IN HEMATOLOGIC MALIGNANCIES. (A) The cancer stem cell (CSC) model assumes a hierarchical structure akin the normal hematopoietic hierarchy. The CSC can give rise to the hematopoietic lineage but usually results in a differentiation block leading to the accumulation of immature progenitor (blast) cells. (B) The clonal evolution model suggests that a carcinogen-induced change in a normal cell confers a growth advantage to that cell permitting its clonal expansion. Selective pressures are responsible for some mutant subclones to expand while others become extinct or dormant. A combination of both models is also possible. *(A, Adapted from Wang J, Ma Y, Cooper MK. Cancer stem cells in glioma: challenges and opportunities. Transl Cancer Res. 2013;2:429. B, Adapted from Nowell PC. The clonal evolution of tumor cell populations. Science. 1976;194:23–28.)*

repopulated secondary NOD/SCID recipient mice and fully reproduced AML.[651,652] Next-generation sequencing efforts have revealed the clonal evolution in primary and relapsed AML.[336,383,394,653–656] While healthy and AML genomes contain hundreds of exonic mutations,[336] as few as two key somatic "driver" mutations enable clonal expansion of a cell that takes along all the background "passenger" mutations. An additional driver mutation occurring in this clone then gives rise to the founding LSC.[336] Mutations in either the LSC itself or again its subclones can evolve into the dominating clone in relapsed AML.[653] Genomic profiling of AML patients has yielded strong evidence for the presence of nonmalignant preleukemic HSPCs[335,395,657] that survive chemotherapy and produce mature lymphoid cells while at the same time generating new waves of mutant clones as the disease progresses. Mutations in epigenetic genes, for instance *DNMT3A*, *IDH2*, and *ASXL1*, are often identified in the ancestral clones, suggesting their early role in AML pathogenesis, whereas mutations in *NPM1* and signaling genes appear to be acquired later.[335,395] Of note, *DNMT3A* and *ASXL1* are also among the three most recurrently mutated genes in clonal hematopoiesis (along with *TET2*) and present with a frequency of about 10% of healthy people over 65 years.[658,659] Furthermore, these findings indicate that the LSC crucial for driving the progression to AML can be a downstream progenitor (in this case, a GMP and/or multilymphoid progenitor). Further support comes from mouse models: LSCs from leukemias initiated by forced expression of an *MLL-AF9* fusion gene (common in AML patients) in GMPs retain the identity of the progenitor cells, despite having acquired self-renewal potential.[373] The identification of both tumor-initiating ancestral HSPCs and LSCs has important implications for the treatment of hematologic malignancies, as relapse-causing clones may be unrelated to the predominant clones at diagnosis in ~50% of patients with B-cell acute lymphoblastic leukemia (B-ALL), T-ALL, and AML.[395]

The combination of advanced mouse models and genetics have yielded a refined understanding of the hematopoietic cells of origin for specific subsets of leukemia. Furthermore, LSCs have been shown to leverage HSC properties to support their survival and expansion.[660] Specifically, Luo et al.[661] demonstrated that aberrant activation of the HOX gene-associated long non-coding RNA, HOTTIP, increased HSC self-renewal, leading to an AML-like disease in mice. Activation of this long non-coding RNA transformed HSCs into LSCs by reprogramming leukemic-associated chromatin and gene transcription.[661] Expression of the fusion oncogenes, ETO2-GLIS2, in fetal HSCs was shown to induce acute megakaryoblastic leukemia, while expression of the same oncogenes in adult HSCs caused a myeloid shift but a delayed leukemogenic transformation.[662] In an analysis of 434 primary human AML samples, Boileau et al.[663] reported the increased frequency of H3 histone mutations and the presence of such mutations in "pre-leukemic HSC," suggesting that such mutations preceded the evolution to secondary AML in these patients. Vu et al.[664] developed a conditionally inducible mouse model in which the caudal-related homeobox transcription factor, Cdx2, was overexpressed in HSPCs. This led to features of MDS with subsequent progression to acute leukemia associated with additional driver mutations.[664] The stage of hematopoietic cell differentiation at which oncogene expression occurs also appears to impact sensitivity to therapy. Cai et al.[665] discovered that expression of oncogenic transcription factor, EVI1, in HSCs produced leukemic cells with decreased apoptotic priming, attenuated p53 response, and resistance to LSD1 inhibitors. These results suggest that the cell of origin for acute leukemias may dictate disease responsiveness to antileukemic therapies. Other studies have demonstrated that myeloid progenitor cells are the cells of origin for common types of leukemia, including MLL-AF9 leukemia.[666] Chen et al. showed that the rapid cell cycle of myeloid progenitors makes them permissive for transformation by MLL-AF9 oncogene.[666] Basilico et al. further characterized the transcriptional profile of multipotent HPCs transformed by expression of MLL-ENL and the molecular relationship between parental HPCs and leukemic cells post–oncogene expression.[667] Di Genua et al. also demonstrated that acute erythroid leukemia arises from combined mutations in CEBPA and Gata2 zinc finger 1 (Znf1) in a neutrophil-monocyte progenitor cell population.[668] Taken together, these studies confirm the heterogeneous nature of the cellular origins of myeloid leukemias and suggest new targets for therapeutic interventions.

CHAPTER 10

MITOCHONDRIA AND HEMATOPOIESIS

Luena Papa

> *Without mitochondria, nothing would exist of the world we know and love*
>
> Nick Lane.

MITOCHONDRIAL STRUCTURE AND FUNCTION

Mitochondria are very complex and highly dynamic organelles. Although responsible for only 10% of the cellular proteome, mitochondria serve not only as powerhouse of the cells but also as critical regulators of essential cellular processes including iron-sulfur cluster biosynthesis, calcium homeostasis, and cell death; hence they contribute to health and disease.

Mitochondria are surrounded by a double-membrane system, consisting of an inner mitochondrial membrane (IMM) and outer mitochondrial membrane (OMM) separated by an intermembrane space (IMS). The inner membrane forms numerous folds (*cristae*), which extend into the interior or the matrix of the organelle (Fig. 10.1). Each of these subcompartments plays distinct functional roles.

Mitochondria use almost 90% of O_2 consumed by the cell to generate adenosine triphosphate (ATP) through oxidative phosphorylation (OXPHOS). During this process, pyruvate that is generated by conversion of glucose in the cytosol is transported into the mitochondria, where it enters the tricarboxylic acid (TCA) cycle and becomes oxidized to yield acetyl coenzyme-A (CoA). Acetyl CoA is also generated by oxidation of fatty acids via the TCA cycle. The series of reactions implicated in the TCA cycle, which occur in the mitochondrial matrix, result in generation of critical metabolites that are further transported into the cytoplasm, where they provide the building blocks for biosynthesis of macromolecules such as nucleotides, lipids, and proteins.[1]

In addition to metabolites, the completion of the TCA cycle is also coupled to reduction of NAD^+ and FAD to NADH (nicotinamide adenine dinucleotide, reduced) and $FADH_2$ (flavin adenine dinucleotide, reduced), respectively. Both of these molecules are then transferred along the "respiratory chain," also known as the "electron transport chain" (ETC). Specially, NADH and $FADH_2$ feed the ETC complex I and II, respectively, which then further transfer electrons to complex III and IV of the ETC. Such electron transfer through the four multisubunit protein complexes of ETC embedded in the IMM generates a proton gradient across the inner membrane that is used by complex V to synthesize ATP through OXPHOS (see Fig. 10.1).[1]

Mitochondrial proteins and hence their functions are originated and controlled by two distinct genetic systems: nuclear deoxyribonucleic acid (nDNA) and mitochondrial (mt)DNA. The majority of the mitochondrial proteins (~1158) are nuclear-encoded proteins. They are imported as unfolded polypeptide chains into the mitochondria through complex mechanisms that mainly rely on the translocase TIM/TOM (translocase of the inner membrane/translocase of the outer membrane) system. These newly synthesized polypeptides contain specific signaling sequences, which direct and target them into distinct mitochondrial subcompartments (mitochondrial matrix, IMM, or IMS) where they undergo proper folding. Unlike the nDNA, mtDNA is simple and lacks both introns and histones. According to the endosymbiotic theory, the simplicity of mtDNA is a result of engulfment of a proteobacterium by another archeabacteria. The resulting double-membrane organelle was capable of producing ATP and providing the host with energy. Over time, however, most of the genetic material was either transferred to the host's genome or lost. These events resulted in the double-stranded, circular mtDNA molecule, which consists of 16,569 base pairs. The main DNA coding sequence is the 1.1 kb loop and consists of two promoters for mtDNA transcription and an origin for replication. mtDNA encodes for only 37 genes of which 13 are structural subunits required for OXPHOS, 2 mitochondrial ribosomal (r)RNAs, and 22 mitochondrial transfer (t)RNAS, essential for synthesis of these subunits.

MITOCHONDRIAL DISEASES

The pathophysiology of mitochondrial diseases is complex and is characterized by defects in OXPHOS. These defects can be triggered by mutations in either nDNA or mtDNA and hence in genes responsible for both the structure and function of mitochondria. As such, complex genetics that underlie mitochondrial diseases can display several patterns of inheritance, including autosomal and X-linked inheritance due to nDNA mutations and maternal inheritance for mtDNA mutations. Because multiple copies of mtDNA are present in each cell, mutations can affect all (known as homoplasmy) or a portion of mtDNA content (termed heteroplasmy). The levels of heteroplasmy vary between cells of the same tissue or organ and from organ to organ. Interestingly, 1 in 200 healthy individuals carry the 10 most common pathogenic mtDNA mutations, although at low levels of heteroplasmy. However, rare, de novo mutations have also been observed. Originally thought to be extremely rare, mitochondrial diseases have now been reported to affect 1 in 4300 people. Mitochondrial diseases are characterized by a high morbidity and mortality because they often involve multiple systems, particularly those that heavily rely on mitochondrial metabolism (Fig. 10.2). However, in a relatively small number of cases, single organ involvement such as isolated ocular involvement in Leber hereditary optic neuropathy (LHON) has been also observed. The heterogeneity of the clinical manifestations makes both the diagnosis and treatment extremely challenging.

The onset of mitochondrial diseases has been reported to have a bimodal distribution reaching a peak in the first 3 years of life followed by a second peak that begins by the end of teenage years and extends to the fourth decade of life. Childhood-onset mitochondrial diseases are usually severe, although not always fatal. These diseases are often caused by recessive nDNA mutations or mtDNA mutations, which are present with very high levels of mtDNA heteroplasmy. Several syndromes that are due to mitochondrial abnormalities, including Leigh syndrome characterized by symmetric spongiform degeneration of the corpus striatum and brainstem with demyelination and vascular proliferation; Alpers-Huttenlocher characterized by epilepsy, psychomotor regression, and liver disease; Pearson syndrome and congenital lactic acidosis; and progressive pure myopathy or a spinal muscular atrophy-like phenotype, arise during childhood. In addition, some forms of renal cystic disorders, proximal tubulopathy, and hypertrophic cardiomyopathy that occur in children have also been attributed to mitochondrial defects.

In this context, Pearson syndrome that was first described in 1979 by Howard Pearson at Yale University (see Chapter 30) is of special interest to hematologists. It is characterized by a mutation in mitochondrial DNA that leads to transfusion-dependent sideroblastic

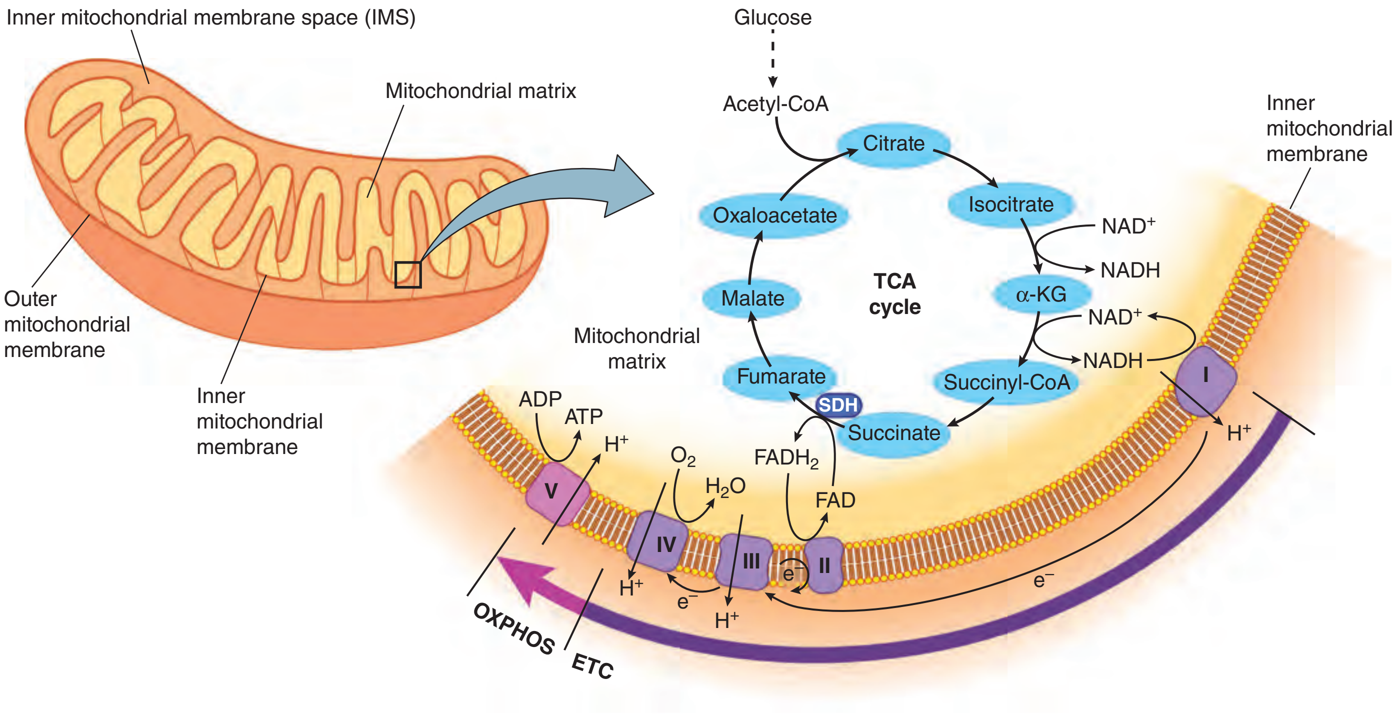

Figure 10.1 MITOCHONDRIAL SUBCOMPARTMENTS, ETC, AND TCA CYCLE. A mitochondrion is composed of an outer (OMM) and inner membrane (IMM), which folds into the interior of matrix to form cristae. The four multisubunit protein complexes (complexes I–IV) of the electron transport chain (ETC) as well as complex V that synthesizes adenosine triphosphate (ATP) are embedded in the IMM *(black square)*. Pyruvate that is generated by conversion of glucose in the cytosol is transported into the mitochondria where it enters the citric acid (TCA) cycle and becomes oxidized to yield acetyl coenzyme-A (CoA). The series of enzymatic reactions of the TCA cycle, which occurs in the mitochondrial matrix, results in the generation of indicated metabolites. The completion of the TCA cycle is also coupled to reduction of NAD^+ and FAD to NADH (nicotinamide adenine dinucleotide, reduced) and $FADH_2$ (flavin adenine dinucleotide, reduced), respectively. Both are then transferred along the ETC. Specially, NADH and $FADH_2$ feed the ETC complex I and II, respectively, which then further transfer electrons to complex III and IV of the ETC. Such electron transfer results in generation of a proton gradient across the IMM known as mitochondrial membrane potential that is then used by complex V to synthesize ATP. This process requires the presence of oxygen and it is known as oxidative phosphorylation.

anemia, vacuolization of marrow precursor cells, and exocrine pancreas dysfunction. Affected individuals experience failure to thrive, pancreatic fibrosis with insulin-dependent diabetes and exocrine pancreatic deficiency, muscle and neurologic impairment, and frequently, early death during infancy. The few patients who survive into adulthood often develop symptoms of Kearns-Sayre syndrome. Less than 100 cases of Pearson syndrome have been reported. In infants, Pearson syndrome is associated with large mtDNA deletions ranging in size from 1.1 to 10 kb. Such mtDNA deletions may occur de novo or be transmitted in a maternal inheritance pattern. The mother of the child, although clinically unaffected, may potentially harbor a great degree of mtDNA deletions in a population of her oocytes. If the mother is clinically unaffected, the risk for the other siblings is estimated to be 1% to 4% because of the possibility of maternal germline mosaicism. Because mitochondria are maternally inherited, offsprings of a male with an mtDNA pathogenic variant are not at risk of inheriting the condition. Prenatal testing for pregnancies at increased risk is available, but results are not reliably predictive of disease severity. Intriguingly, several isogenic immortalized pluripotent stem cell (iPSCs) lines derived from cells of a patient with Pearson lacked detectable levels of the deleted mtDNA, whereas other lines had a great degree of deletions. The iPSCs carrying a high burden of deleted mtDNA displayed differences in proliferation, mitochondrial function, and hematopoietic phenotype when differentiated in vitro, as compared with isogenic iPSC which lacked the deleted mtDNA.[2]

Interestingly, a study of a cohort of 178 infants with Diamond-Blackfan anemia showed that 4.8% of them actually had Pearson syndrome. The identification of Pearson syndrome is not insignificant because patients with Diamond-Blackfan anemia are empirically treated with corticosteroids, which do not benefit patients with Pearson syndrome and may lead to infectious and metabolic complications.[3]

Mitochondrial diseases can also present and progress in several ways during adult life. The abnormalities in an affected adult patient often do not fit into a specific syndrome because mitochondrial disease can encompass multiple systems of the body. Patients with Kearns-Sayre syndrome, a progressive cradioencephalomyopathy, in infancy can be clinically manifested as Pearson syndrome, whereas in middle age the patients develop chronic progressive external ophthalmoplegia (CPEO). Multiple endocrinopathies involving the adrenal gland, pancreas, thyroid, and parathyroid gland frequently develop in patients with more severe disease.

Neurogenic muscle weakness, ataxia, and retinitis pigmentosa (NARP) syndrome, a progressive neurologic disorder, forms a clinical continuum with maternally inherited Leigh syndrome. NARP is caused by a mutation in mtDNA involving specifically the *MT-ATP6* gene. Individuals with heteroplasmy levels of greater than 70% to 90% clinically manifest NARP, whereas those with greater than 90% present Leigh syndrome. Leigh syndrome becomes apparent during the first year of life, whereas the first symptoms of NARP syndrome begin in childhood or early adulthood. Together, this pattern of disease indicates the complexity and the marked clinical variation of disease manifestations observed in patients, which frequently delays both diagnosis and appropriate clinical care. has dramatically advanced the diagnosis and increased our understanding of the molecular landscape and the genetic basis of these disorders. Many novel therapeutic approaches are being explored in preclinical models, and several new therapies are being evaluated in ongoing clinical trials. Despite this success, many challenges remain, including understanding of the mechanisms implicated in the phenotypic expression of a particular genetic defect as well as the optimal care for patients with mitochondrial diseases. In this chapter, we will review the role of mitochondria in both normal and abnormal hematopoiesis, as well as in aging.

MITOCHONDRIAL REGULATION OF HEMATOPOIETIC STEM CELL FATES

Hematopoiesis relies on the integrity of a unique pool of hematopoietic stem cells (HSCs). HSCs and specifically those with long-term (LT) hematopoietic reconstitution capabilities occupy the apex of the hematopoietic system. They sustain LT hematopoiesis throughout the lifespan of an individual by constantly replenishing the hematopoietic system with committed progenitors and differentiated blood cells. Vast numbers of all types of adult mature hematopoietic cells (10^{11} to 10^{12}) are continuously generated each day through a series of lineage-committed progenitor cells.[4] The LT regeneration capacity is due to HSCs' ability to balance the self-renewal with differentiation. Such balance is central to blood cell homeostasis and is regulated by the complex interplay of cell-intrinsic and cell-extrinsic signaling networks.[5] This interplay is orchestrated and controlled by the mitochondrial network, which recently has emerged as a critical determinant of HSC homeostasis, commitment, and differentiation.

During homeostasis, HSCs are predominantly quiescent. To meet the physiologic demands for mature cells during steady-state condition, HSCs exit the quiescent state and become activated into slowly dividing cells.[6] Upon hematopoietic stress that occurs after acute depletion of progenitors and mature hematopoietic cells, HSCs rapidly enter the cell cycle and proliferate to replace the depleted cells. The exit of HSCs from quiescence, and their proliferation and commitment to multiple different cell fates, are intrinsically coupled with altered cellular metabolism and mitochondrial activity (Fig. 10.3).[7] It has been postulated that a metabolic switch from glycolysis to mitochondrial OXPHOS precedes the transition of HSCs from quiescence to proliferation. However, evidence has demonstrated that priming of quiescent HSCs and their entry into the cell cycle appears to be accompanied by upregulation of glycolysis.[8] Because glycolysis is linked to mitochondrial metabolism, such an increase in glycolysis rate might provide the energy required for entrance of quiescent HSCs into the cell cycle and activation of the mitochondrial network. Increased mitochondrial activity is essential for actively dividing HSCs and their commitment into each type of lineage-differentiated hematopoietic cells. In fact, compromised mitochondrial function and perturbation of metabolic pathways result in impaired differentiation and leukemia.[9]

Metabolic cues and mitochondrial content and activity vary drastically within different stages of hematopoiesis. LT HSCs are characterized by low mitochondrial mass, mitochondrial membrane potential (MMP), and reactive oxygen species (ROS) as opposed to committed progenitors and differentiated mature cells. The increase in the mitochondrial activity upon cell commitment allows the differentiating cells to meet their altered high metabolic and bioenergetic demands. Such metabolic rewiring is accompanied by profound alterations in the mitochondrial ultrastructure and dynamics, both of

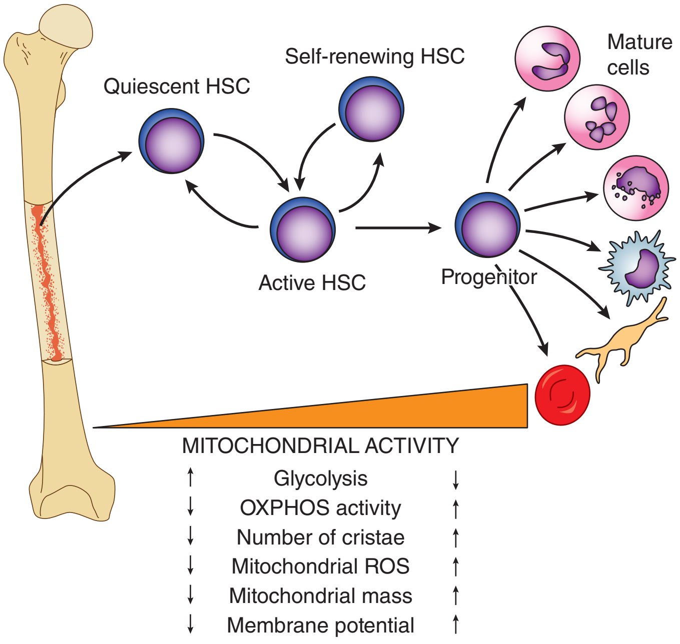

Figure 10.3 MODEL OF HEMATOPOIESIS. Quiescent hematopoietic stem cells (HSCs) reside in the bone marrow (BM) niches and rely mainly on glycolysis for their energy production. Upon hematopoietic stress, HSCs exit the quiescent state and become activated into slowly dividing HSCs, giving rise to a daughter cell that may remain in the cell cycle or give rise to a daughter cell that may return into a quiescent state to maintain the pool of primitive HSCs. Frequent and rapid cell divisions lead to transiently amplifying progenitors, which in turn give rise to more differentiated effector hematopoietic cells. A metabolic switch associated with an increased level of mitochondrial oxidative phosphorylation activity, reactive oxygen species generation, membrane potential, and mass occurs during the course of differentiation. *(Adapted from Papa L, et al. Ex vivo HSC expansion challenges the paradigm of unidirectional human hematopoiesis.* Ann NY Acad Sci. *2020;1466[1]:39–50.)*

which determine HSC fates.[6] Indeed, mitochondrial dynamics, morphology, and metabolism reciprocally influence each other to maintain the balance between self-renewal and proper differentiation of HSCs.[10] Impairment of mitochondrial metabolism affects mitochondrial dynamics and morphology, resulting in loss of HSC quiescence and self-renewal potential.[11] Conversely, aberrations in mitochondrial dynamics compromise the capacity of HSCs to differentiate into lymphoid cells.[6,12]

Beyond OXPHOS and ATP generation, mitochondria drive HSC fate decisions by regulating biosynthesis and the epigenome. Mitochondrial metabolites generated by OXPHOS and TCA cycles control DNA methylation, chromatin remodeling, and posttranslational modifications of various proteins, including histones and other epigenetic factors. In turn, such changes shape the epigenetic landscape and affect gene repertoires, ultimately compromising HSC function and cell fates.[1]

Mitochondria are signaling organelles that govern HSC fate decisions by also regulating calcium homeostasis and pathways involved in inflammation and cell death. In fact, each of these pathways is differently impacted by various levels of mitochondrial ROS.

Although mitochondria are the major source of ROS generation, they are also the main targets of ROS. Mitochondrial DNA and the mitochondrial proteome (mitochondrial and nuclear encoded proteins) are particularly vulnerable to ROS-mediated damages. This is due in part to their close proximity to the ETC, which is the primary site of ROS generation. A subtle elevation in ROS levels, in part, triggers HSC commitment and differentiation. Alternatively, excessive ROS levels impair HSC multilineage differentiation and induce uncontrolled proliferation and sustained cumulative damages, leading to HSC exhaustion, loss of self-renewal potential, and cell death.[6]

Unlike other cellular compartments, mitochondria are poorly equipped with quality control elements such as chaperones and proteases, which monitor proper protein folding and eliminate misfolded and oxidative damaged proteins. Accumulation of such damaged proteins further impacts the ETC activity and electron leakage from ETC, leading ultimately to increased ROS levels. The increased ROS levels, in turn, can trigger vicious cycles of mitochondrial damage and sustained energetic catastrophe. To reduce oxidative and metabolic stress that can be detrimental for HSC fates and integrity, HSCs use complex regulatory pathways and defense mechanisms[6] that are summarized in Fig. 10.4.

In the following sections we will discuss each of these topics and review the latest advances in our understanding of the multiple mechanisms by which the mitochondrial network controls stemness and differentiation of HSCs during normal hematopoiesis, leukemic transformation, and regeneration.

The Mitochondrial Unfolded Protein Response Mechanism

HSCs have a low protein synthesis rate and a limited folding capacity in comparison with committed progenitors and differentiated cells.[13] To achieve rapid and effective blood cell replacement with various hematopoietic progenitor and differentiated cells, HSCs face a burst in mitochondrial biogenesis. This burst is accompanied by an increased need for protein synthesis.[14] Due to the poor folding capacity, the increase in protein synthesis can exceed and overwhelm the capacity of the protein quality control system, leading to mitochondrial proteostasis stress, increased oncogenic transformation, and impaired HSC regenerative potential. To cope with the mitochondrial proteostatic stress, mitochondria signal the stress to the nucleus. Such events establish the mitochondria-to-nucleus signaling crosstalk, which result in the activation of the mitochondrial unfolded protein response (UPRmt). The UPRmt acts by coordinating the function of several pathways, all of which culminate in induction of proteases and chaperones that are required for proper protein folding and their complex assembly. Thus UPRmt monitors transcriptional programs and critical pathways that ensure overall mitochondrial fitness and integrity. A recent study identified a novel arm of UPRmt in HSCs, which is regulated by the coordinated interplay of Sirtuin (SIRT7), a histone deacetylase, and nuclear respiratory factor 1 (NRF1), a master regulator of mitochondrial biogenesis.[15] In response to bioenergetic stress, HSCs activate SIRT7, which represses the activity of NRF1. In turn, this suppression reduces mitochondrial translation and biogenesis and alleviates stress. Remarkably, SIRT7 expression, which is downregulated with aging, is

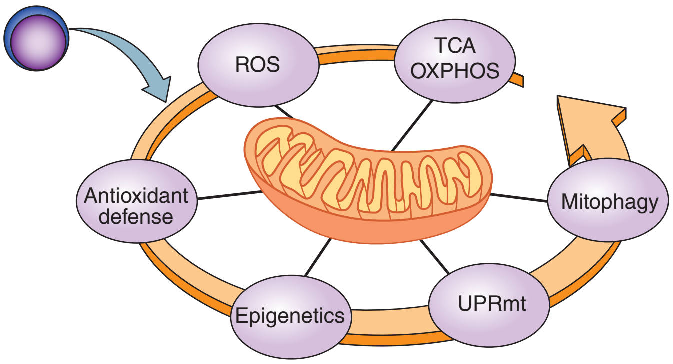

Figure 10.4 MECHANISMS OF MITOCHONDRIAL CONTROL OF HEMATOPOIETIC STEM CELLS (HSCS). Mitochondria activate and coordinate multiple and complex mechanisms to regulate the self-renewal potential of HSCs and their cell fate decisions. Under homeostasis and stress conditions, mitochondria controls HSC fate by regulating the OXPHOS activity and reactive oxygen species (ROS) production, activating mitophagy, mitochondrial unfolded protein response, antioxidant defense, as well as shaping the epigenomic landscape of HSCs.

associated with reduced HSC regenerative capacity.[15] In fact, in aged HSCs, mitochondrial protein folding stress is also linked to activation of NLR family pyrin domain containing 3 (NLRP3) inflammasome.[16] Repression of the NLRP3 inflammatory pathway by activated SIRT2, a cytoplasmic deacetylase, regulates the functional deterioration of aged HSCs.[16] Failure to engage UPRmt can irreversibly damage HSC cellular and metabolic fitness, leading to increased ROS generation, uncontrolled HSC proliferation and differentiation, and loss of HSC integrity and cell death.[15]

The Mitochondrial Oxidative Self-Defense Response Mechanism

Stringent regulation of ROS levels in HSCs is a complex process and relies on activation of the antioxidant defense mechanisms. As discussed earlier, ROS regulates HSC fate decisions by acting as rheostats. To maintain low ROS levels, HSCs engage multiple antioxidant pathways. Activation of such pathways are tightly coupled to redox sensors, including thioredoxin-interacting protein (TXNIP) and magnesium superoxide dismutase (MnSOD).[6,7] Intriguingly, upon transient and low levels of oxidative stress and ROS, TXNIP alters the function of p53 from acting as a prooxidant to an antioxidant. A limited activation of p53 mediates activation of ROS scavengers, including MnSOD and Sestrins. In addition to p53, several other molecular pathways have been reported to act as central hubs that control both metabolism and the redox state of HSCs. Of great interest in this regard are both Forkhead box O3 (FOXO3) and p38 mitogen-activated protein kinase (MAPK) cascade. Loss of FOXO3 resulting in ROS-dependent activation of p38 compromises the mitochondrial activity, redox state, and metabolism and hence leads to a decline of the LT repopulating capacity of HSCs.[17]

Remarkably, both FOXO3 and p53 activities are controlled by the family of Sirtuins, in particular SIRT1, a deacetylase that requires NAD⁺ for its activity. By deacetylating both histone and nonhistone proteins, including key transcription factors, SIRT1 modulates metabolism, cellular signaling pathways, and the epigenome in HSCs. Following metabolic stress, SIRT1 mitigates high ROS levels in part by activating SIRT3, a mitochondrial deacetylase that regulates the global acetylation of mitochondrial proteins.[18] Induced SIRT3 expression can rejuvenate aged HSCs due to enhanced mitochondrial antioxidant defenses.[6] Together, this evidence underscores the ability of HSCs to integrate multiple and complex pathways, all of which are required to activate antioxidant defense pathways and thereby preserve their LT self-renewal potential.

Mitochondrial Dynamics Controls the Self-Renewing Potential of Hematopoietic Stem Cells

HSC fate decisions are also regulated by dynamic changes in mitochondrial networks, which are highly dynamic and undergo continued remodeling and changes in shape and architecture. This dynamic remodeling, which contributes to mitochondrial quality control and mitochondrial fitness, is orchestrated by balanced fusion and fission of mitochondria. Human LT HSCs contain mitochondria that are small and globular with few deformed and poorly developed cristae, which reflects their low bioenergetic state (Fig. 10.5). In fact, immature cristae, which are the folded sections of the IMM and house the ETC complexes, are tightly linked to the low degree of respiration, OXPHOS activity, and thus low MMP. Upon HSC commitment and differentiation, mitochondrial network maturation results in the appearance of elongated and filamentous mitochondria with well-developed cristae accompanied by increased MMP and activity. Consistent with this notion is the evidence that loss of imprinting at the DLK1-GLT2 locus, which is associated with increased mature cristae folds, results in enhanced mitochondrial activity, ROS generation, and impairment of HSC LT reconstitution potential.[19] Moreover, increased mitochondrial size and volume due to loss of mitochondrial carrier homolog 2 (MITCH2), which primes mitochondrial OXPHOS activity, result in accelerated differentiation and exhaustion of HSCs.[11]

The fusion and fission machinery relies on the balanced activities of several proteins, including mitofusin 1 (MNF1), MNF2, and dynamin-related protein 1 (DRP1). Disruption of this balance is accompanied by a shift towards fusion and increased MFN2 levels favoring generation of abundant and highly filamentous mitochondrial networks in metabolically activated cells. MNF2 levels are particularly upregulated during commitment and differentiation of HSCs, whereas reduced MNF2 levels result in the maintenance of the HSC pool with retention of lymphoid potential.[12] Changes in mitochondrial shape can be also triggered by the decreased mitochondrial

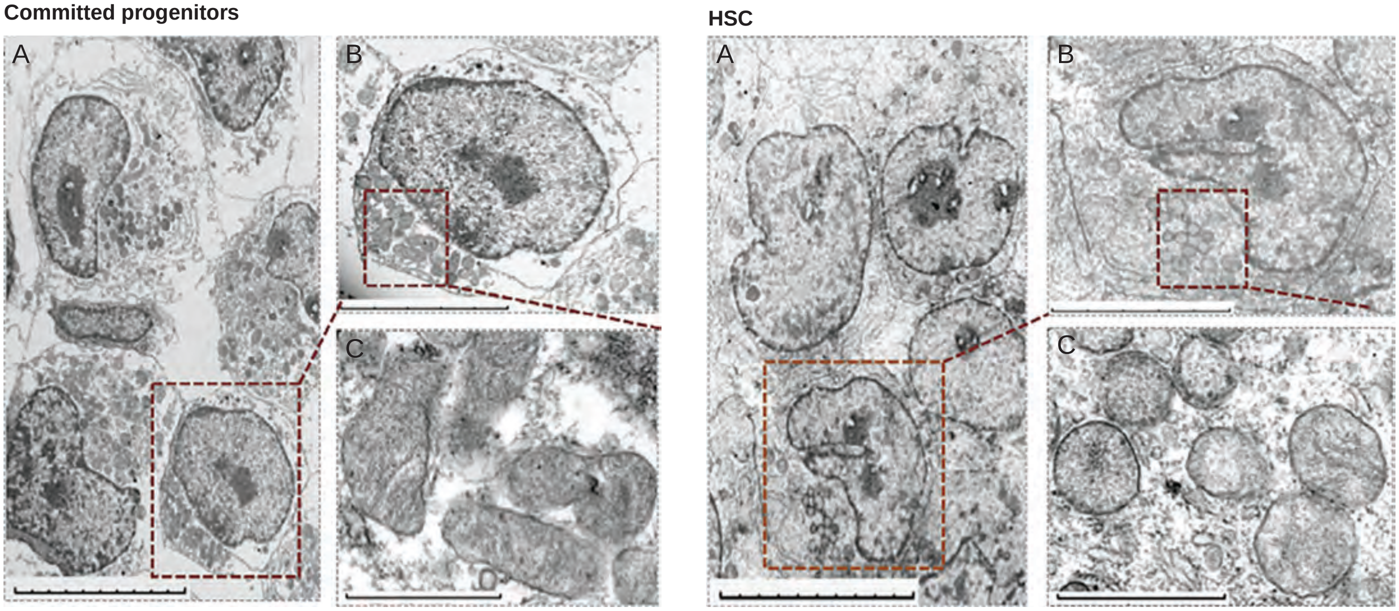

Figure 10.5 MITOCHONDRIAL MORPHOLOGY IN COMMITTED PROGENITORS AND HEMATOPOIETIC STEM CELLS (HSCs). Electromicrographs of committed progenitors *(left panel)* and HSCs *(right panel)*. Committed progenitors contain tubular, elongated-shaped mitochondria filled with regular and high number of cristae. HSCs contain globular, round-shaped mitochondria with low number and deformed cristae. Ex vivo human HSC expansion requires coordination of cellular reprogramming with mitochondrial remodeling and p53 activation. Blood Adv. 2018 Oct 23;2(20):2766–2779.)*

translocation of DRP1, which is a master regulator of mitochondrial fragmentation. Interestingly, loss of MITCH2 and increased differentiation of HSCs is accompanied by reduced levels of DRP1.[11] Collectively, these findings highlight the importance of mitochondrial dynamics and shape in the retention of the pool of LT HSCs and their differentiation capacities.

Mitophagy as a Gatekeeper of Hematopoietic Stem Cells Fate Decisions

The fitness of the mitochondrial network in HSCs is largely controlled by activation of a selective form of autophagy termed mitophagy. Mitophagy acts as a major gatekeeper of metabolic activity in HSCs by selectively removing damaged mitochondria that represent a great threat to both HSC self-renewal potential and integrity. Mitophagy also limits the number of active mitochondria contributing in a reduction of both mitochondrial mass and activity. Although this view has been recently challenged due to the heterogeneity of HSCs, a recent report has reinforced the role of mitophagy in maintaining the pool of LT HSCs.[6] Activation of mitophagy is required for purified HSCs marked by angiopoietin-1 receptor (Tie2) expression to retain their self-renewal potential without lineage bias.[20] In addition, impaired autophagy caused by loss of the autophagy gene, *ATG12*, drives accelerated myeloid differentiation and compromises HSC self-renewal capacity. Specifically, ATG12$^{-/-}$ HSCs contain increased numbers of filamentous mitochondria with enhanced membrane potential, elevated ATP generation, and OXPHOS activity. ATG12$^{-/-}$ HSCs exhibit a skewed ratio of circulating myeloid versus lymphoid cells that resembles the biased HSC differentiation, a characteristic of aged HSCs. Remarkably, aged HSCs with high levels of mitophagy activation display an enhanced repopulating capacity as opposed to aged HSCs.

To rapidly reconstitute the hematopoietic system with differentiated cells upon stress, transplanted HSCs require a boost in their mitochondrial activity. Under stress conditions, retention of the self-renewing HSC pool is tightly controlled by two metabolic checkpoints that involve UPRmt and FOXO3-mediated autophagy.[15,21] This activation results in reduced mitochondrial mass and activity and preservation of the HSC pool. Recent evidence has pinpointed that activation of these mechanisms might depend on SIRT1. Activation of the SIRT1 axis via use of the NAD$^+$-boosting agent nicotinamide riboside (NR) increases HSC regeneration capacity by increasing mitochondrial clearance. This NR-induced mitophagy is required to reduce both MMP and metabolism of HSCs.[4] Collectively, this evidence clearly highlights the role of mitophagy as another critical checkpoint that controls mitochondrial activity and metabolic programs under homeostasis, stress, and HSC transplantation and thus controls and regulates HSC fate decisions.

Mitochondrial Metabolic Regulation of the Epigenetic Landscape of Hematopoietic Stem Cells

HSC fate and function are controlled by mitochondrial metabolic regulation of their epigenetic landscape, which relies on mitochondrial-generated metabolites of the TCA and OXPHOS cycles. Such metabolites act not only as critical regulators of cellular homeostasis but also as cofactors for histone modifiers and other key elements that influence the epigenetic state of HSCs. One of the most prominent metabolites is acetyl-CoA that fuels the TCA cycle to generate ATP. Acetyl CoA also provides the acetyl groups for acetylation of histone tails, resulting in dynamic alterations of the epigenetic state of chromatin. Such alterations also influence the epigenetic control of transcriptional programs and thus impact HSC fate decisions.[1] The epigenomic state of HSCs can also be influenced by the alpha ketoglutarate (αKG), which promotes DNA demethylation. Aberrant DNA demethylation associated with altered αKG levels results in HSC differentiation and aberrant HSC self-renewal.[1]

In addition to the TCA cycle, the epigenetic landscape of HSCs is also controlled by mitochondrial OXPHOS activity. Inhibition of mitochondrial OXPHOS activity decreases histone acetylation and blocks differentiation of HSCs. Impaired HSC differentiation was also observed upon loss of Rieske iron-sulfur protein, an element of the complex III subunit of ETC, that impairs OXPHOS respiration.[9] Notably, repressed respiration was accompanied by accumulation of TCA-derived metabolites such as 2-hydroxyglutarate, fumarate, and succinate, resulting in an increase in both DNA hypermethylation and histone hypoacetylation.[9] In turn, this metabolic imbalance alters both the epigenomic and transcriptomal profiles, resulting in impaired differentiation and depletion of myeloid progenitors. Collectively, these findings point to the regulation of OXPHOS activity and its constant feedback with the TCA cycle, both of which shape the epigenome and determine HSC fates.

Remarkably, the interplay between mitochondrial metabolism and epigenome in HSCs is tightly regulated by SIRTs. Specifically, activated SIRT1 by NAD$^+$ or acetyl CoA acts as a histone deacetylase to regulate chromatin remodeling and achieve silencing of transcriptional programs in HSCs. Loss of SIRT1 results in skewed differentiation of HSCs favoring the myeloid cell lineage. HSCs that lack SIRT1 exhibit a premature aging phenotype and loss of quiescence. Similar effects were observed in HSCs with ablated SIRT6, which epigenetically suppress the transcription of Wnt target genes through deacetylation of histone H3K56.[22]

Thus, in summary, by regulating the flux and proper balance of metabolites and their epigenetic activities, the mitochondrial network serves as a central hub that controls the HSC epigenetic landscape and therefore HSC fate decisions.

INTERACTION OF MITOCHONDRIAL NETWORK WITH THE BONE MARROW MILIEU REGULATES HEMATOPOIETIC STEM CELL FATES

The profound role of mitochondria as critical determinants of HSC self-renewal potential cannot be envisioned without the extrinsic signals imposed on HSC by their bone marrow (BM) niches. To maintain a low metabolic state, mitochondria in HSCs act in close interaction with HSC niches. Primitive HSCs reside not only in extremely hypoxic areas, but also in periarteriolar and highly vascular areas of the BM where oxygen tension is high. Thus, in contrast to previous beliefs, hypoxia does not appear to be the sole mechanism by which the BM niche contributes to retention of LT HSCs. The arterial BM endothelial cells, which are exposed to the highest oxygen tension, create a barrier for quiescent HSCs. The integrity of this barrier is attributed to the ability of endothelial cells to scavenge excessive ROS levels. In addition, endothelial cells of the periarteriolar regions rely mainly on glycolysis to avoid ROS generation. Accordingly, this barrier provides an ROS-low microenvironment to protect the integrity of HSCs.

Mesenchymal stem cells (MSCs), another component of HSC niches, have been also reported to scavenge mitochondria and ROS from HSCs under high oxidative stress conditions. Connexin 43 (CX43), a component of gap junctional channels, mediates the transfer of ROS from HSCs to MSCs, resulting in reduced ROS levels.[6] Alternatively, CX43 facilitates the transfer of mitochondria from HSCs to MSCs. This dynamic mitochondrial transfer inversely regulates low levels of ROS generation and thus contributes to the retention of HSC self-renewal potential.[6] Conversely, transfer of mitochondria from MSCs to HSCs drives the HSC response to acute bacterial infection, resulting in rapid HSC differentiation and leukocyte expansion.[23] Remarkably, such mitochondrial transfer occurs prior to activation of the transcriptional programs that control the burst in mitochondrial biogenesis.[23] The rapid increase in mitochondrial mass and subsequent metabolic changes in HSCs enable their prompt differentiation, resulting in increased leukocyte numbers that are required to successfully fight infection. Thus overall it appears that the mutual transfer of mitochondria between HSCs and BM niche cells acts as an early physiologic response to regulate either HSC self-renewal potential or facilitate the rapid onset of emergency hematopoiesis through HSC differentiation. Together, this evidence highlights the dynamic relationship between extrinsic signals imposed by the BM and intrinsic mechanisms regulated by the mitochondrial network that dictate HSC fate decisions.

MITOCHONDRIAL AND BONE MARROW ROLES IN LEUKEMIC STEM CELLS AND AGED HEMATOPOIETIC STEM CELLS

As discussed earlier, great progress has been reached in our understanding of the plasticity of both BM niches and mitochondrial network, and their coordinated control of HSC fates. Despite major developments, our ability to trace and understand the role of mitochondria in regulating normal HSC fates within the BM microenvironment under stress is limited. In this regard, studies of aged HSCs and leukemogenesis have provided critical insights. With age, HSCs lose their regenerative potential, exhibit unbalanced myeloid differentiation, and frequently become transformed, leading to the development of various hematologic malignancies. Mutations in mtDNA alone cannot account for malignant transformation of HSCs. Aberrant mitochondrial activity and metabolism in concert with an inflamed microenvironment accompanied by a burst of inflammatory chemokines are also critical for HSC aging and their malignant transformation into leukemic stem cells (LSCs). In fact, changes in the BM stroma with age create a permissive environment that supports both leukemic transformation and propagation of their clones. Alternatively, LSCs can directly remodel BM stroma to preferentially permit their survival and uncontrolled proliferation at the expense of normal HSCs. Such remodeling allows for changes in niche structure and a burst of inflammatory cytokines. Together, these events exhaust normal HSCs and enhance LSC survival. Remodeling of the BM microenvironment has been reported in many types of leukemia, including chronic myeloid leukemia (CML), acute myeloid leukemia (AML), and B-cell acute lymphoblastic leukemia. Evidence indicates that the remodeled BM fuels mitochondrial fatty acid oxidation (FAO) metabolism by LSCs, thereby shaping their epigenetic and metabolic landscape. In fact, resistance to several treatment approaches, including the combination of the Bcl2 inhibitor venetoclax with the hypomethylating agent 5-azacitidine, is mediated by the upregulation of mitochondrial FAO. FAO activation reverses the inhibitory effect of this chemotherapy combination on mitochondrial OXPHOS activity of LSCs, allowing them to survive.[24] Notably, LSCs rely both on glycolysis and OXPHOS to meet their bioenergetic demands. Enhanced mitochondrial OXPHOS activity triggered by the mitochondrial transfer from BM MSCs to AML LSC blasts provides them with energy and thus with survival advantages.[25] Intriguingly, mitochondrial transfer to BM MSCs rescues acute lymphoblastic leukemia cells from ROS-inducing chemotherapy and cell death.[26] Therefore targeting the reciprocal dependence of LSCs on perturbed BM niche cells and vice versa might open novel therapeutic treatment avenues to perturb both the epigenome and metabolome of LSCs and overcome chemotherapy resistance. LSC resistance to tyrosine kinase inhibitor (TKI) treatment for CML (see Chapter 69) has been attributed to the role of SIRT1. Specifically, SIRT1 activity enhances mitochondrial OXPHOS and metabolic regulation of LSC maintenance, growth, and resistance due to upregulation of PGC-1α.[27] In fact, these mitochondrial alterations occur independently of kinase activation, and TKI treatment enhanced inhibition of CML hematopoiesis in SIRT1-deleted mice. Collectively, these findings point to the close interplay of the transformed mitochondrial network and the altered BM microenvironment in promoting transformation and resistance of LSCs to various treatments.

MITOCHONDRIAL AND EPIGENOME CONTROL REPROGRAMMING OF HEMATOPOIETIC STEM CELLS

Understanding of the dynamic signaling networks that shape the epigenome and mitochondrial metabolism in HSCs and govern their LT self-renewing potential can undoubtedly lead to advances in regenerative medicine and stem cell therapy. HSC transplantation has been used as therapy for patients with blood disorders and refractory hematologic malignancies. Different sources of HSCs, including mobilized peripheral stem cells and BM, can be used for HSC transplantation. Unfortunately, difficulties in human leukocyte antigen matching and graft-versus-host disease or other forms of immune rejection limit the use of HSCs for stem cell therapy. In this context, umbilical cord blood (UCB) can be used as an alternative source. However, the inadequate number of HSCs within a single UCB unit and the inability of many cytokine cocktails to expand the number of UCB LT HSCs in ex vivo cultures represent a major limitation for their use in clinical settings. Currently, various ex vivo expansion strategies, including stemreginin 1 (SR1), pyrimidole derivative UM171, and valproic acid (VPA), have been successfully implemented in ongoing clinical trials. Although most of these ex vivo strategies expand the number of existing HSCs present within UCBs, the VPA strategy has been reported to also trigger cellular reprogramming of committed progenitors into HSCs (Fig. 10.6). In fact, VPA is clearly an excellent example that tightly links shaping of the epigenome with altered transcriptome and mitochondrial metabolism in LT HSC. VPA, which is a deacetylase inhibitor, alters the epigenome and regulates the transcriptional programs of UCB $CD34^+$ cells. This altered transcriptome greatly resembles the transcriptomic profiles that characterize unmanipulated LT HSCs.[7] Intriguingly, cellular reprogramming by VPA is accompanied by remodeling of the mitochondrial network characterized by low mass, MMP, and activity. Such a restructured mitochondrial network is reminiscent of mitochondria of unmanipulated LT HSCs. Both acquisition and maintenance of LT HSCs were influenced by the antioxidant activity of the p53-MnSOD axis. Likewise, activation of autophagy in cultures of UCB HSCs expanded with SR1 or UM71 may further improve expansion of LT HSCs.[28] Moreover,

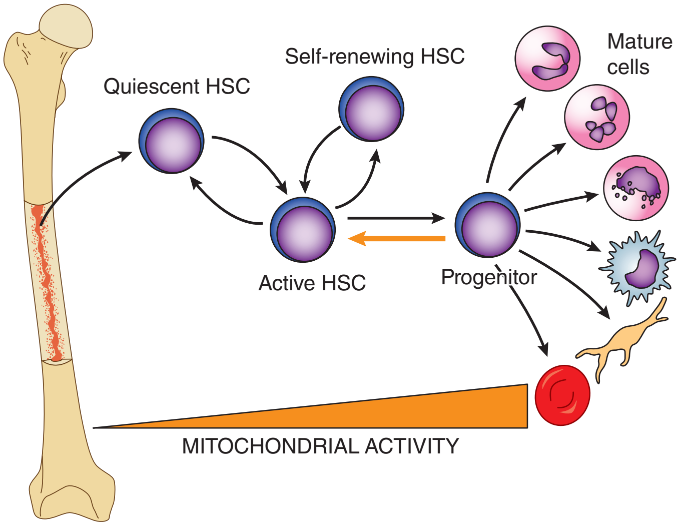

Figure 10.6 CELLULAR REPROGRAMMING OF COMMITTED PROGENITORS INTO HEMATOPOIETIC STEM CELLS (HSCs). Valproic acid (VPA) triggers rapid reprogramming of committed progenitors into functional HSCs by altering their epigenome, transcriptome, and mitochondrial profile. The reprogrammed HSCs exhibit a reduced mitochondrial activity and profile that closely resembles that of the unmanipulated HSCs. *(Adapted from Papa L, et al. Ex vivo HSC expansion challenges the paradigm of unidirectional human hematopoiesis.* Ann NY Acad Sci. *2020;1466(1):39–50.)*

NR treatment that regulates metabolic and mitochondrial fitness by inducing mitophagy might prove useful as a potential booster of hematopoiesis, not only following ex vivo HSC expansion cultures but also in vivo in patients with BM aplasia and myelodysplastic syndromes where age-dependent mitochondrial defects have been observed.[4]

CONCLUDING REMARKS

Clearly, the ability of the mitochondrial network to integrate intrinsic signals with cues from the microenvironment and control the epigenome and metabolism of young HSCs, aged HSCs, and LSCs is emerging as a key aspect of stem cell biology. A further comprehensive characterization of how the coordinated interplay of these signaling networks governs HSC fates and their plasticity under both homeostasis and hematopoietic stress will undoubtedly lead to potential novel strategies for promoting self-renewal of healthy HSCs in aging and during ex vivo HSC expansion. On the other hand, identifying the key metabolic cues and mitochondrial mechanisms that control LSC fate decisions will likely lead to new pathways and targets to deplete their numbers.

CHAPTER 11

CYTOKINES, CHEMOKINES, OTHER GROWTH FACTORS, AND THEIR RECEPTORS

Hal E. Broxmeyer[†] and Maegan L. Capitano

INTRODUCTION

Hematopoiesis is regulated by cytokine-cell and cell-cell interactions.[1] Cytokines are polypeptides secreted by many cell types either constitutively or after induction and are usually classified based on primary structures associated with their receptor extracellular domains.[2,3] They regulate a large range of biologic functions, including hematopoiesis, immunity, and inflammation. In context of hematopoiesis, they have effects on proliferation, differentiation, survival/cell death (apoptosis), and cell movement/migration/induced mobilization. They can act in a paracrine fashion on closely adjacent cells, cells at a distance in the same tissue area, or other tissue areas sometimes by their movement from one tissue/organ to another tissue/organ. Cytokines can also work in an autocrine fashion. A rigorous definition of autocrine regulation is that the cytokine works within the cell that produces it, and either maintains the cytokine for internal cellular signaling/activity or can release it, upon which it can then act on the same cell that produced and released it. Autocrine regulation is a much-discussed mode of action, especially in leukemia and other cancers, but in reality it is very difficult to prove this concept of a cell. Many papers that have referred to autocrine production/action have not rigorously proven this concept, even in the case of leukemia or other cancers. Paracrine modes of action refer to the situation when proteins are secreted/released by a cell and then act on another cell, which is more easily proven and verified.

To modify an old proverb: "What is forgotten is doomed to be repeated without gain of new knowledge." Many current investigators do not cite or even know of crucial past efforts in the field of how cytokines, chemokines, and other growth-modulating factors influence hematopoietic stem cell (HSC) and hematopoietic progenitor cell (HPC) cell biology and of hematopoietic cell regulation. Thus they unfortunately lose out on knowledge that could help their research. For this reason, this review references the older, as well as more recent, literature on cytokines/interleukins (ILs)/chemokines, other growth factors, and their effects on cell regulation. Although this includes an extensive list of references, it is not an exhaustive list.

After many years of intensive research going back to at least the 1960s, it is recognized that cytokines are widely pleiotropic, with numerous cases of redundancy in action and with many overlapping functions. In fact, there are few cytokines that have been shown to have only one cell and mode of action, including production/release of other growth modulating factors, and it is likely even these few such cytokines will eventually be shown to be pleiotropic in action/activity. Individual cytokines can act as agents that induce either positive and/or negative effects or, when used in combination, additive to synergistically positive and/or negative effects. These different actions are sometimes dependent on the target cells(s) of action and depend on how they are combined for in vitro and in vivo assessments. It is highly likely that combined effects of cytokines occur with great frequency during in vivo regulatory events and in context of the microenvironment niche in which they are produced/released (e.g., in the bone marrow [BM]). Moreover, a cytokine can induce the production/release of other cytokines that can then produce effects that were originally ascribed to the cytokine that started this cascading set of regulatory events. Only by studying effects of cytokines at the single isolated target cell level, with and without serum/plasma (to eliminate effects of growth modulating factors present in serum/plasma) can one begin to truly understand the initial target cell(s) and the action(s) of the cytokine(s) of interest. Thus reductionist approaches of unraveling cytokine cell action(s) are more frequently used, as is single-cell ribonucleic acid (RNA) sequencing (RNA-seq), which is used to assess intracellular events. However, ultimately, to fully and clearly understand hematopoiesis and its regulation, it is necessary to put data together in a total context of interacting cytokines and target cells to get a more accurate picture of what is happening at a physiologic and pathologic level. This is necessary to better use our knowledge for eventual enhanced clinical efficacy for treatment of both malignant (e.g., leukemia, lymphoma) and nonmalignant (e.g., preleukemia, myelodysplastic syndromes [MDS], and myeloproliferative neoplasms [MPNs]) diseases.

Cytokines act through specific cell surface receptors to activate intracellular events, with some receptors acting in concert with other receptors to elicit their regulatory effects.[4,5] It is notable that as late as the mid-1970s not much was known about specific growth factors, other than that for erythropoietin (EPO), the red blood cell hormone, which was the first growth factor to be purified. Recombinant growth factors were not yet produced or known. Growth factors were identified by their purported actions present in crude preparations of cell or tissue extracts or in media conditioned by cells or tissues. The biologic activities attributed to these cell/tissue extracts or conditioned media could have been and, in fact, were in many cases due to combinations of proteins, and one had to rule out effects of confounding and contaminating agents such as bacterial lipopolysaccharide (LPS).[6] In fact, this contamination of even "purified" protein products is still a confounding problem because LPS can stimulate release of cytokines. An example of these growth regulatory factors were the terms for these activities: colony-stimulating activity (CSA), colony-inhibiting activity (CIA), or colony-stimulating factor (CSF), even before it was known what these proteins were. Presently, through biochemical purification procedures and then later through recombinant deoxyribonucleic acid (DNA) technology, the proteins from these crude preparations responsible for these biologic activities were found to include, in addition to EPO, the CSFs: granulocyte-macrophage (GM)-CSF (also known as CSF-2), granulocyte (G)-CSF (also known as CSF-3), interleukin-3 (IL-3) (previously termed multi-CSF), macrophage (M)-CSF (also known as CSF-1), and thrombopoietin (TPO). The CIA molecules were later identified as lactoferrin (LF), H-subunit (H)-ferritin, and some of the ILs, interferons (IFNs), tumor necrosis factors (TNFs), transforming growth factors (TGFs), and a large number of other, now well-defined and characterized, proteins. We now know that GM-CSF, G-CSF, IL-3, M-CSF, EPO, TPO, and two potent costimulating molecules, stem cell factor (SCF) and Flt3-ligand (FL), transmit their cascade of intracellular signaling molecules after binding to specific receptors (R). GM-CSFR is: GM-CSF-alpha (α), subunit cluster density (CD)116; G-CSFR is: CSF3R/CD114; IL-3R is: IL-3RA/CD123; M-CSFR is: tyrosine kinase CSF1R/c-FMS/CD115; EPO has two receptors, those on hematopoietic cells and those on other cells[7]; the TPOR is: myeloproliferative leukemia protein (MPL)/CD110; SCFR is: the tyrosine kinase c-kit/CD117 and is found as both a cell membrane and soluble protein; and FLR is: the tyrosine kinase, Flt3.

[†] Deceased

Class or type I cytokines (often referred to as hematopoietins) regulate development, differentiation, and activation of hematopoietic and immune cells. Their receptors are type I membrane proteins with an N-terminal extracellular and C-terminal intracellular orientation. Type I cytokine receptors include receptors for CSFs, ILs, EPO, TPO (Fig. 11.1),[5] and hormones such as growth hormone (GH) and leptin.

Class II cytokines consist of type I IFNs, which include 16 members that are produced by almost every nucleated cell, with approximately 20% to 60% sequence identity, including 12 subtypes of IFN-α, IFN-β, IFN-ε, IFN-κ, and IFN-ω. Type I IFNs initiate signaling by binding to the same receptor composed of two subunits called IFNAR1 and IFNAR2. Type II IFN consists of the single IFN-ϒ, which signals through a heterodimeric receptor composed of IFNGR1 and IFNGR2. Type III IFNs include IFN-λ1 (IL-29), IFN-λ2 (IL-28A), and IFN-λ3 (IL-28B). Some include the IL-10 family of cytokines (IL-10, IL-19, IL-20, IL-22, IL-24, IL-26) within the group of type III IFNs. The type III IFN receptor is composed of IL-10Rβ and IL-28R (Fig. 11.2).[5]

Structural similarities between the various type I cytokines were not immediately recognized. However, cloning of their receptors revealed significant homology in that the extracellular regions contain a common domain with four conserved cysteines (C4) in the N-terminal segment and a tryptophan-serine doublet near the C-terminal end.[3] Mutagenesis studies revealed a structural role for these amino acids

Figure 11.1 CLASS OR TYPE I CYTOKINES (OFTEN REFERRED TO AS HEMATOPOIETINS) REGULATE DEVELOPMENT, DIFFERENTIATION, AND ACTIVATION OF HEMATOPOIETIC AND IMMUNE CELLS. Simple depiction of type I cytokine receptor subfamilies. Interleukin (IL)-3 receptor (R), IL-5R, and granulocyte-macrophage colony-stimulating factor receptor (GM-CSFR) share a common βc chain that places them in one group. IL-12 family members include four cytokines. IL-12 and IL-23 share the IL12Rβ1 unit, and IL-12 and IL-35 share the IL-12Rβ2 unit. IL-27 shares gp130 with the IL-6 family. Multiple cytokines (IL-2, IL-4, IL-7, IL-9, IL-15, IL-21) share the common Rγ chain, which is mutated in a subset of patients with severe combined immune deficiency. IL-4R shares a subunit with IL-13R. Both IL-4 and IL-13 drive T helper 2 (Th2) responses. IL-7R shares one subunit with the thymic stromal lymphopoietin (TSLP). This sharing of receptor subunit may explain why deletion of the gene encoding IL-7R affects the lymphoid system more severely than deleting the IL-7 gene. The IL-6 family includes multiple cytokines that all have the signal transducer gp130. Deleting gp130 results in embryonic lethality. Some IL-6 family members activate more than one receptor. Oncostatin M (OSM) can work through a heterodimer receptor consisting of gp130 with OSMRβ or gp130 with leukemia inhibitory factor receptor (LIF-R). Ciliary neurotrophic factor (CNTF), cardiotrophin-like cytokine (CLC), and neuropoietin (NP) engage the receptor composed of gp130, LIFR, and CNTFR. Cardiotrophin-1 (CT-1) uses a receptor composed of gp130, LIF-R, and another, yet to be identified subunit. IL-27 shares gp130 with its specific receptor unit. IL-31 receptor is composed of gp130-like receptor (GPL) and OSMRβ.

Figure 11.2 SCHEMATIC DIAGRAMS OF INTERLEUKIN (IL)-1, IL-17, AND TYPE II CYTOKINE FAMILY MEMBERS AND RECEPTORS. IL-1 family and receptors. The IL-1 family is associated with acute and chronic inflammation and plays an essential role in the host response to infection. IL-1α and IL-1β share the same receptor. IL-33 and the IL-36 subfamily share with IL-1 and the IL-1R3 receptors *(top panel)*; IL-17 family and receptors. IL-17 secretion defines the T helper 17 (Th17) cells that mediate host defensive mechanisms to various infections and that are involved in the pathogenesis of many autoimmune diseases. The five IL-17 receptors are not homologous to any known receptors and show considerable sequence divergence. They harbor extracellular domains composed of fibronectin type III domains and cytoplasmic SEFIR (a.k.a. SEF/IL-17R) domains that show loose homology to Toll–IL-1R domains *(middle panel)*; and type II cytokine receptor family. These include receptors for interferons (IFNs) and the IL-10 family *(lower panel)*.

in maintaining tertiary receptor structures without being involved in cytokine interactions. A 200-amino-acid region evolutionarily derived from a tandem of two ancestral fibronectin-like domains were named hematopoietin receptor domain or cytokine-binding homology region (CHR) because they mediate interactions with cytokines. α-Receptors of IL-2 and IL-15 of the γc family are atypical cytokine receptors; they do not contain a CHR, but rather they contain sushi domains. Two conserved Box 1/ Box 2 regions are located in the proximal intracytoplasmic segment (Fig. 11.3). By contrast, type II cytokine receptors contain two cysteine doublets (C2-C2) located in the C-terminal end of both fibronectin-derived domains. They retain Box 1/2 regions but lack a tryptophan-serine-x-serine-tryptophan motif. Both types of receptors bind ligands that display common spatial four α-helix bundle organizations; they use intracellular signaling mediators of Janus kinase (JAK) and signal transducer and activator of transcription (STAT) families.[5] Type I and II cytokine receptors represent homogeneous structural groups of proteins. Sequence homology is noted in limited numbers of cases, including for GH/prolactin (PRL) and for the IL-6 families. Evidence of the common derivation of cytokines is observed in a common four-helix bundle structures, in addition to similar intron-exon relationships and clustering observed for certain cytokine genes, such as genes of the IL-4 family.[8] Receptors can be composed of dimers of a single chain G-CSFR, EPO receptor (EPOR), or TPOR (c-MPL) or are heterodimeric with a common signaling subunit and a unique ligand-binding chain. Heterodimeric receptors are grouped into families based on sharing a common β-chain GM-CSFRα, IL-3Rα, IL-5Rα, or sharing a gp130 receptor (IL-6Rα, leukemia inhibitory factor [LIF] receptor β, ciliary neurotrophic factor receptor α [NTFRα], IL-11Rα IL-12R, IL-23R, oncostatin M receptor α) or sharing a common γ-chain (IL-2Rα, IL-2Rα, IL-4Rα, IL-7Rα, IL-9Rα, IL-13Rα, IL-15Rα, and IL-21Rα) (see Fig. 11.1).[5]

CYTOKINES AND THEIR MODIFYING INFLUENCES

Many CSFs have been implicated in the pathobiology of both hematopoietic and nonhematopoietic disorders or have been used

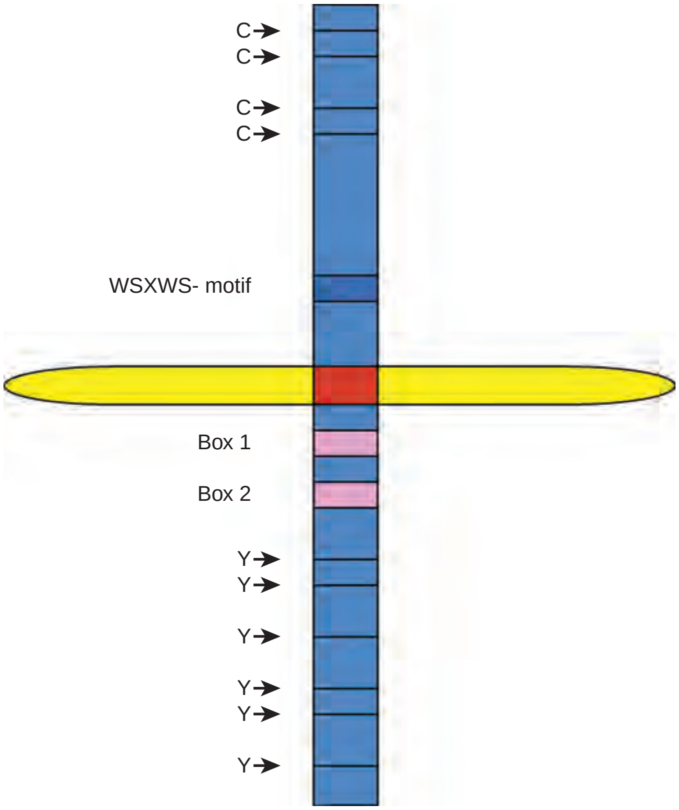

Figure 11.3 CYTOKINE RECEPTOR SUPERFAMILY. The general structure of cytokine receptor superfamily. In the extracellular cytokine receptor module, four conserved cysteine residues exist and are involved in disulfide bonds. A WSXWS (Tre, Ser, any, Tre, Ser) motif that is essential for receptor processing, ligand binding, and activation of the receptor is also located in the extracellular domain. In the intracellular portion, two short domains termed *Box 1* and *Box 2* are important for Janus kinase (JAK) binding. Tyrosine residues are present on the intracellular part to be phosphorylated upon receptor activation. Yellow oval represents the plasma membrane.

after production by recombinant DNA technology to treat patients. Cytokines are involved in regulation of hematopoiesis at the level of HSC, HPC, and more mature blood or other accessory cells. Accessory cells include stromal cells (which are themselves very heterogenous), endothelial cells, cells belonging to lymphoid lineages (T cells, B cells, natural killer [NK] cells, NKT cells), and innate immune cells (monocytes/macrophages, neutrophilic myeloid cells, dendritic cells [DCs]). Cell regulation is not necessarily easily dissectible, but strides have been made in elucidating these intricate cytokine-cell interactions. Cytokine receptor signaling has been reviewed.[3,5,8] Cytokines are involved in developmental processes during embryogenesis, through neonatal, and into adult life. They can fight infections and elicit immune responses. Redundancy in cytokine(s), their receptors, and actions are probably nature's way to protect the body against unwanted insults that may interfere with specific cytokines and their protective actions. ILs and chemokines are part of the cytokine superfamily of molecules. ILs, chemokines, and their receptors are covered in this chapter, as will other biologically active proteins that influence hematopoiesis. Cytokines are secreted by leukocytes, as well as other cells. They act on, but are not limited to, hematopoietic cells to regulate blood cell production; this includes effects on immune cells and during inflammation. Biologically active proteins influence in vitro and in vivo proliferation, differentiation, and survival/apoptosis (programmed cell death) at the level of HSC, HPC, and more mature cells of the hematopoietic system. It is clear that activities of these proteins can be modified by enzymatic cleavage, such as that mediated by dipeptidylpeptidase (DPP) 4 (a.k.a. CD26), and also in context of oxygen tensions that are vastly different in vivo (~1% to 5% O_2 in BM, and also low in blood and other tissues, from that of the ambient air conditions of ~21% O_2 in which most investigators have studied the in vitro and ex vivo activities of these growth regulators). These potent cytokines/chemokines/other growth regulators and their receptors are discussed throughout the chapter. It is not possible to truly understand the action(s) of cytokines and other growth-modulating factors in absence of these modulating/modifying influences on cytokine activities.

Importantly, cytokine-cell interactions can become dysregulated and induce or be involved in pathologic situations. Examples of some adverse pathologic effects of cytokines include the "cytokine storm" elicited following chimeric antigen receptor (CAR) T-cell therapy, during inflammation,[9] and after infection with viruses, such as SARS-CoV-2 (see Chapters 26, 67, 68, 79, 90, and 152).[10–13] Thus cytokine-cell interactions present a "double-edged sword" for both "good" (physiologic) and "bad" (pathologic) effects. Specific information on cytokines, chemokines, iron-binding proteins, other biologically active proteins, and growth regulation and their receptors follows.

SPECIFICS OF GROWTH-MODULATING FACTORS

There are many cytokines, including CSFs, ILs, and chemokines, which are enumerated as follows.

Colony-Stimulating Factors

Much of the original background on CSFs through the mid to late 1980s has been reviewed,[14–17] but it is important to understand that the purification and respective cloning of the ligands and receptors of GM-CSF,[18–23] G-CSF,[24,25] IL-3,[26–33] M-CSF,[34–45] EPO,[46–51] and TPO[52–55] have led to the preclinical analyses of their biologic activities in vitro and in vivo,[56–75] and the eventual evaluation of their effects in humans. For example, EPO has been used to enhance erythropoiesis and production of erythrocytes in humans under a variety of clinical scenarios,[76,77] GM-CSF, G-CSF, and TPO have been used to accelerate production of myeloid cells,[78–89] and G-CSF has also been used to mobilize HSC and HPC for eventual collection as autologous and allogeneic stem cell grafts.[90,91]

Interleukins

The IL family of cytokines now includes IL-1 through IL-38/40,[92–99] with the first IL, IL-1, purified to homogeneity in 1977.[94] Examples of some of the actions of the ILs and the cell(s) that produce them are summarized in Table 11.1. ILs are placed in different families based on sequence homology, receptor similarities, and their functional activities. Some of the IL receptors are shown in Fig. 11.4.[93] Many ILs, as do most members of the cytokine family, have redundant activities and have multiple effects on immune cells and hematopoiesis. Reviews on the IL-1,[94,100] IL-2,[101] IL-6,[95,96] IL-10,[97] IL-12,[98] and IL-17[99] families present in-depth information on many of the known IL molecules. Examples of the hematopoietic actions of some of the ILs from our lab and others, such as IL-1,[102–106] IL-3,[107–109] IL-4,[110,111] IL-5,[112] IL-6,[113–120] IL-7,[121,122] IL-8 (also known as the chemokine CXCL8),[123] IL-9,[124–126] IL-10,[127–129] IL-11,[130] IL-12,[131] IL-17,[132] IL-18,[133] IL-20,[134] IL-21,[135,136] IL-26,[137] IL-31,[138] IL-32,[139–142] and IL-33,[143–147] have been reported. The receptor for IL-33 is known as suppressor of tumorigenesis (ST2) which is primarily elevated during graft-versus-host disease (GVHD) and is a biomarker associated with a poor prognosis.[148–153] IL-33 signaling is also associated with hematologic malignancies, autoimmune disorders, allergic inflammation, and gastrointestinal cancers.[154–158] The ILs work in combination with other ILs, as well as other cytokines, to regulate hematopoiesis in an additive to synergistic fashion.

TABLE 11.1 Interleukins

Interleukin (IL)	Produced By	Actions
IL-1	Macrophages, B cells, endothelium, fibroblasts, astrocytes	Activates lymphocytes, stimulated macrophages; increases leukocyte/endothelial adhesion
IL-2	T cells	T and B cells proliferation and differentiation; activates NK cells antibody production
IL-3	T cells	Acts as a multi-CSF
IL-4	CD4$^+$ T cells (Th2)	Acts on T and B cells
IL-5	CD4$^+$ T cells (Th2)	Activates eosinophils and production of innate immune cells
IL-6	T and B cells, fibroblasts, macrophages	B-cell differentiation
IL-7	BM stromal cells	Acts on pre-B cells and T cells; stimulates B- and T-cell proliferation
IL-8	Monocytes and fibroblasts	Targets include mature myeloid cells
IL-9	Th9, Th2, Th17, Mast, NKT and TREG cells	Enhances survival of T cells and activates mast cells
IL-10	Th2 cells	Primary targets are Th1 cells; down regulates Th17 cells, and inhibits macrophage IL-12 production
IL-11	BM stromal cells and fibroblasts	Actions on hematopoietic progenitors and osteoclasts
IL-12	Monocytes	Induces Th1 cells, and T cells, and NK cell IFN-γ production
IL-13	Th2, NKT, and mast cells	Acts on monocytes, epithelial cells, and B cells
IL-14	T cells	Activates B cell proliferation and inhibits secretion of immunoglobulins
IL-15	Monocytes, epithelium	Acts on T cells and activated B cells
IL-16	CD8$^+$ T cells and eosinophils	CD4$^+$ T-cell chemoattractant
IL-17	Th17 cells	Acts on epithelial and endothelial cells; causes release of cytokines
IL-18	Macrophages	Cofactor in Th1 cell induction; induces IFN-γ and enhances NK cell activation
IL-19	Th2 cells, antiinflammatory molecules	Antiinflammatory molecule involvement
IL-20	Immune cells and activated epithelial cells	Plays a role in cellular communication
IL-21	NK and CD4$^+$ T cells	Acts on innate and adaptive immune cells, and erythroid progenitor cells
IL-22	T cells and other cells in the innate and acquired immunities	Inhibits IL-4 production
IL-23	Macrophages and dendritic cells	Maintenance of IL-17–producing T cells
IL-24	Monocytes and T and B cells	Involved in wound healing and protects against bacterial infections
IL-25	Dendritic cells	Th2 cells and their production of IL-4 and IL-13
IL-26	Th17 cells	Causes IL-10, IL-1β, IL-6, and IL-8 production
IL-27	T cells	Proinflammatory molecule
IL-28	TREGs	Acts on keratinocytes and melanocytes
IL-29	Virus-infected cells, dendritic cells, TREGs	Upregulates viral protective responses
IL-30	Monocytes in response to Toll-like receptor agonists such as bacterial lipopolysaccharides	Acts on many hematopoietic cells
IL-31	Th2 and dendritic cells	Acts as proinflammatory and chemotactic factor
IL-32	NK cells and monocytes	Induces cytokine production (IL-6, IL-1β) and inhibits IL-15 production
IL-33	Mast cells and Th2 cells	Mediates Th2 responses
IL-34	Phagocytes and epithelial cells	Enhances IL-6 production and is involved in differentiation of antigen-presenting cells
IL-35	Regulatory B cells	Immune suppressor
IL-36	Phagocytes	Acts on T and NK cells
IL-37	Phagocytes	Regulates innate immunity and causes immunosuppression
IL-38	Placenta, B cells, etc.	Acts on T cells, inhibits IL-17 and IL-22 production
IL-39	B cells	Acts on differentiation and expansion of neutrophils
IL-40	BM, fetal liver, activated B cells	Involved in development of humoral immune responses

BM, Bone marrow; *CSF*, colony-stimulating factor; *IFN*, interferon; *NK*, natural killer; *Th*, T helper; *TREG*, T regulatory.

Figure 11.4 CYTOKINE RECEPTORS. (A) Receptors for the interleukin (IL)-2 family (IL-2, IL-4, IL-7, IL-9, IL-15, IL-21); (B) receptors for IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF); (C) receptors for IL-4 and IL-13; (D) IL-10 receptor family members (IL-10, IL-19, IL-20, IL-24, IL-26, IL-28, IL-29); (E) tumor necrosis factor (TNF)-α (TNFR1, TNFR2) and transforming growth factor (TGF)-β (TGF-βR1, TGF-βR2) receptors; (F) IL-12 receptor (IL-12 β1 plus IL-12Rβ3), IL-23 receptor (IL-12Rβ plus IL-23R); and (G) interferon (IFN)-α and IFN-β bind IFNAR1 plus IFNAR2, and IFN-β also binds R1 plus IFN-γ R2 heterodimers. *(From Akdis M, Aab A, Altunbulakli C, et al. Interleukins (from IL-1 to IL-38), interferons, transforming growth factor β, and TNF-α: Receptors, functions, and roles in diseases. J Allergy Clin Immunol. 2016;138(4):984–1010, Fig. 1.)*

Chemokines and Chemokine Receptors

Chemokines, originally considered chemotactic cytokines, are a large family of cytokines that usually signal through G protein–coupled heptahelical receptors (Table 11.2 and Fig. 11.5).[159–161] There is redundancy within the chemokine family, with some chemokines binding multiple chemokine receptors and, in more rare occasions, nonchemokine receptors, and some chemokine receptors binding multiple chemokines. Fig. 11.6 diagrammatically denotes the many functions of chemokines and chemokine receptors.[159] Chemokines can act as monomers but can form homodimers,[162] heterodimers, and higher aggregates. Specific chemokines and their receptors have been implicated in various phases of HSC regulation.[163–166] They can act as positive and negative regulators of HSC and HPC and have been implicated in the survival, proliferation, and mobilization of these cells.[162,167–197] For example, IL-8/CXCL8, which acts through the chemokine receptors CXCR1 and CXCR2, has been implicated not only in the negative regulation of hematopoiesis,[176] but CXCL8 and CXCR2 have been implicated in leukemia/MDS.[195–197] Interestingly, DEK, a heterochromatin remodeling agent that has cytokine-like activity, can bind and signal through the chemokine receptor CXCR2 and can compete with IL-8/CXCL8, as well as macrophage inflammatory protein (MIP)-2, at the level of CXCR2.[196,197] Extracellular DEK potently enhances cytokine-induced ex vivo expansion of mouse BM and human cord blood (CB) HSCs,[196] plus has other effects.[198,199] Another well-recognized chemokine and its receptor is SDF-1/CXCL12 and CXCR4, respectively.[179–199] stromal cell-derived factor (SDF)-1/CXCL12 is involved in normal and leukemic HSC/HPC survival, proliferation, chemotaxis, migration, and mobilization. SDF-1/CXCL12 also binds to CXCR7,[192] but CXCR4 appears to be the main hematopoietic signaling receptor for SDF-1/CXCL12. Blocking of CXCR4 by the CXCR4 antagonist, AMD3100/plerixafor, has been used to induce the mobilization of peripheral blood HSC and HPC and to synergize with G-CSF in this mobilization.[90,187] Chemokines are affected by a number of posttranslational modifications,[159] including by DPP4, which is discussed later in this review. They are inducible by several different stimuli and are involved and are players in response to infection and inflammation.[159,160] There are also viral genes that encode chemokine receptors.[200] Chemokine receptors can also regulate infectivity to viruses. For example, individuals with specific mutations in CXCR5 are immune or less susceptible to infection with human immunodeficiency virus (HIV), but thus far only very few patients with HIV have been “cured” by allogeneic stem cell transplantation using donor cells from stem cell donors with this specific variant of mutated CXCR5.

The complex network of cytokines and chemokines and their overlapping and diverse effects on a variety of cellular processes is truly incredible and goes beyond regulation of normal cells.[201–207] Although redundant chemokine/chemokine receptor interactions are likely the body’s way to protect itself, this “protection” can elicit serious consequences. Many chemokines and their receptors are part of the triggered cytokine release syndrome (CRS), which represents a side effect following CAR-T-cell therapy and viral infections, such as that induced by SARS-Cov-2 during COVID-19 infections.[208–214] These events lead to excessive elaboration of chemokines and other cytokines and their receptors, representing the “double-edged sword” discussed earlier in terms of health benefits and disease-related problems. Greater knowledge of the production and actions of chemokines, and their intracellular signaling cascades that are induced through chemokine and cytokine receptors, is crucial for future benefits for normal cell regulation and their modification and to dampen their adverse effects during disease.

Role of Nuclear Factor-κB in Cytokine and Chemokine Gene Regulation, Inflammation, Immunity, and Cancer

NF-κB (nuclear factor kappa-light chain enhancer of activated B cells) is a protein complex controlling transcription of DNA, as well as cytokine production and cell survival.[215] NF-κB is involved in cellular responses to stress, cytokines, irradiation, and bacterial or viral antigens. Aberrant NF-κB regulation is associated with cancer, inflammation, autoimmune diseases, septic shock, viral infection, and disordered development of immune cells. In an inactivated state, NF-κB is located in the cytosol with inhibitory protein IκBα. Through a variety of extracellular signals including cytokine and chemokine, the enzyme IκB kinases is activated, which then phosphorylate IκBα, resulting in ubiquitination dissociation of IκBα from NF-κB and degradation of IκBα by the proteasome. Activated NF-κB then translocates to the nucleus and binds to specific sequences of DNA termed response elements. The DNA/NF-κB complex recruits other proteins. There are numerous NF-κB target genes that include cytokines, chemokines, and their modulators (see https://www.bu.edu/nf-kb/gene-resources/target-genes/). Upstream signal transduction of NF-κB activation has been described.[216] Reviews and articles are reported on a role for NF-κB in cytokine gene regulation,[217] chemokine gene transcription, and tumor growth,[218] inflammation, cancer, multiple myeloma, and thrombosis.[218–222] Many inhibitors of NF-κB signaling have been described.[223] Overall, the impact of NF-κB on cytokines and chemokines and resultant physiologic and pathologic effects cannot be underestimated. With the multitude of cytokines and other factors that can influence NF-κB signaling, it is not at all surprising that NF-κB can regulate hematopoiesis. NF-κB has been shown to play an important role in the differentiation of HSCs and HPCs down both the myeloid and lymphoid pathways. The Rel/NF-κB transcription factors are mainly composed of five members (c-Rel, p65/RelA, RelB, NFKB1/p50, NFKB2/p52). P65 and p50 are ubiquitous proteins expressed in all hematopoietic lineages. However, the distinct expression pattern of the other Rel/NF-κB factors in HPCs indicates their importance in HPC differentiation. Lymphocytes, monocytes, granulocytes, and erythrocytes express c-Rel. RelB is mostly expressed in DCs and lymphocytes. DCs, macrophages, and lymphocytes express p52. Using mouse knockout animal models, investigators have shown the importance of these factors in regulating hematopoietic differentiation.

Engineered Cytokines and Role of Cytokines and Other Reagents for Preclinical and Clinical Ex Vivo Expansion of Hematopoietic Stem Cells and Hematopoietic Progenitor Cells

Cytokines and/or chemokines when combined have additive to synergistic effects on proliferation of HPCs.[224–233] This is especially so for the potent costimulating cytokines SCF (which acts through the c-kit receptor)[234–249] and FL (which acts through the FL3 receptor).[250–259] Efforts have been made to specifically engineer cytokines and chemokines for greater efficacy.[260,261] This includes the GM-CSF/IL-3 fusion protein, PIXY32,[262,263] which has been used in a clinical trial to promote hematopoietic recovery following chemotherapy-induced multilineage myelosuppression in patients with sarcoma,[264,265] as well as IL-3/EPO,[266] and IL-8/PF4[174] fusion. These have had only limited clinical testing.[265] By contrast, molecularly engineered forms of small molecule agonists of the thrombopietin receptor (eltrombopag and romiplostim) are currently used to treat patients with immune thrombocytopenic purpura as well as aplastic anemia (see Chapters 31 and 128).

Enhancement of ex vivo expansion of HSCs/HPCs for both preclinical[267–280] and clinical use[272–285] is an ongoing area of research. Current clinical trials on ex vivo expansion have been described.[285] There are currently three sources of cells that have been used for clinical HCT. This includes BM, cytokine- and/or other reagent-induced mobilized peripheral blood, and umbilical cord blood. There have been a number of preclinical studies to expand numbers of CB HSCs and HPCs ex vivo. Some such as SR1, UM171, nicotinamide, prostaglandin $(PGE)_2$ analog, and other reagents are currently in clinical trials.[282–286] None of the ex vivo expansion procedures work without

addition of combinations of cytokines such as SCF, TPO, and FL during the ex vivo culture period. Hence there is a need to add the reagent(s) of choice with SCF, TPO, and FL during the ex vivo culture period. Importantly, use of serum-free cultures and a short time of cell culture has benefits for potential use of the generated cells for clinical application. What is clear is that the most effective ex vivo expansion studies for clinical use is not yet known. Moreover, there are numerous other ex vivo expansion studies not yet tested clinically, and which of these may eventually be the procedure of choice for clinical use is as yet unknown.

OTHER GROWTH MODULATING PROTEINS/FACTORS

Iron-Binding Proteins

Although mainly known for their iron-binding capacity and influence on metabolism of iron, LF, transferrin, and H-ferritin also play a role in the regulation of hematopoiesis.[287–331] The iron-binding proteins LF,[295–312] transferrin,[313–315] and H-ferritin[316–331] have been implicated by in vitro and in vivo studies in the regulation of hematopoiesis. LF, originally named for being found in breast milk, has been shown to directly and/or indirectly suppress the production/release of CSFs from monocytes and macrophages and also to directly suppress hematopoiesis at the level of HPCs.[295–305] For LF suppressive activities to occur, the LF must be fully iron saturated.[295] Transferrin also suppresses release of growth factors but from subsets of lymphocytes.[314,315] H-ferritin has direct suppressive actions on HPCs mediated by its ferroxidase activity, and the iron content of H-ferritin does not appear to be required for its myelosuppressive activity.[331] The receptors for LF and H-ferritin have not been definitively defined to date.

Transforming Growth Factor-β, Associated-Inhibin Family Members, Bone Morphogenic Protein, Tumor Necrosis Factor-α, and Interferons

Transforming Growth Factor-β

TGF-β isoforms 1, 2, and 3 are part of a family of factors that influence growth and differentiation of cells with the capacity to both inhibit and/or stimulate growth.[332,333] TGF-β was originally isolated as a factor that induced cellular transformation and anchorage-independent fibroblast cell line growth.[334] Its many functional activities have been described.[332–345] Intracellular signaling of TGF-β through its receptors has been reported.[332] Although involved in normal cell regulation, abnormalities of the signaling of TGF-β have been associated with a number of diseases, including cancer.[333] Mammalian genomes encode 33 polypeptides related to known TGF-β family polypeptides. These include, among others, the activins (activin and inhibin which are discussed later), bone morphogenetic proteins (BMPs 2 to 10),[346–348] growth and differentiation factors (GDFs 1, 3, 5, 6, 7, 9, 10, 11, and 15), and nodal. Numerous studies have assessed roles for TGF-β in both positive and negative regulation of hematopoiesis and the immune system.[333–345] Modulation of the effects of TGF-β has been explored to treat HSC defects and BM failure states including Fanconi anemia and myelofibrosis.[349]

Inhibins (Activin and Inhibin)

Inhibins, belonging to the TGF-β family of polypeptides, are heterodimeric proteins that consist of an inhibin α and inhibin β chain, whereas activins are homodimers of inhibin/activin β chains. There are different inhibin chains (α and β) that have roles in a variety of developmental, physiologic, and disease states.[350,351] Activin has enhancement activity for erythroid progenitor cells (e.g., burst-forming unit–erythroid [BFU-E]) in vitro and in vivo, whereas inhibin has suppressive effects on BFU-E in vitro and in vivo.[352–355]

Bone Morphogenetic Protein

BMPs,[346–348] members of the TGF-β family, are secreted extracellular matrix (ECM) proteins that regulate a wide variety of development processes. They have been associated with a number of human disease states and in stem cell and organ formation,[356] but their role in hematopoiesis has yet to be rigorously elucidated.

Tumor Necrosis Factor

TNF was originally named for its capacity to cause the necrosis of selected tumors; it is derived from lymphocytes and macrophages and is distinguishable from lymphotoxin (LT).[357,358] TNF is also a powerful cachexia-inducing factor associated with the devastating cachexic wasting side effects of the progression of cancer,[359] and a pathogenetic role for TNF-α was proposed for the development of cachexia, arthritis, and autoimmunity due to tristetraprolin deficiency.[360] When the gene encoding tristrapolin is disrupted in mice, the animals develop a severe syndrome of arthritis, autoimmunity, cachexia, dermatitis, and myeloid hyperplasia. The severe inflammatory syndrome which accompanies loss of tristetraprolin function in mice is in part the result of TNF-α messenger RNA (mRNA) stabilization and hypersecretion; TNF family members play numerous negative and positive regulatory roles in hematopoiesis—some modulated by ligand/receptor intracellular events that cause the release of a number of other cytokines, each with their different effector functions.[361–367] There are large numbers of the TNF and TNF receptor superfamily members including, but not limited to, the receptors: CD40, FAS, KD30, 4-1BB, CD27, RANK, and the ligands (L): CD40L, FasL, OXr40L, Light, 4-1BBL, CD276, LT, Tweak, April, RANKL, and TRAIL/Apo2L.[356]

Interferons

IFNs form another large family of related molecules. IFN were originally described as antiviral agents, but have since shown to have a large variety of actions that can have positive or negative effects on the hematopoietic and immune systems, through direct and indirect actions that are well documented.[367–372] Indirect effects include induction of the release of other biologically active proteins.[372] The inhibitory effects of IFN-α have been exploited to treat patients with MPNs (see Chapter 70).

Additional Growth Modulating Factors

There are a number of other proteins and their families that also regulate cell growth. These include, but are not necessarily limited to, angiopoietins,[373] angiopoietin-like molecules,[374] adipocytokines,[375] epidermal growth factor (EGF),[376] fibroblast growth factor (FGF) and its receptors including FGF23 and FGFR3,[377–381] glial cell line–derived neurotrophic factor (GDNF), nerve growth factor (NGF),[382] early growth response (EGR)-1 proteins,[383] vascular endothelial cell growth factor (VEGF),[384,385] macrophage-stimulating factor (MSF),[385] DEK,[196–198] oncostatin M,[386] macrophage migration inhibitory factor,[387,388] and pleiotrophin. Pleiotrophin (PTN), also known as heparin-binding brain mitogen, heparin-binding growth factor 8, neurite growth-promoting factor 1, heparin affinity peptide, and heparin-binding growth factor–associated molecule, is an 18-kDa growth factor with an affinity for heparin. PTN is encoded by the PTN gene and is structurally related to midkine and retinoic acid–induced heparin-binding protein (see https://en.wikipedia.org/wiki/Pleiotrophin).[389] PTN has numerous effects on hematopoiesis, including retention and self-renewal of HSCs in the BM vascular niche,[390] HSC maintenance and regeneration,[391] and involvement in regulation of HSC/leukemia stem initiating cells from patients with chronic myeloid leukemia.[392] Leptin (Lep) and LepR have also been implicated in stem cell regulation at the level of the BM microenvironmental niche,[393] and LepR-positive BM HSCs have a high level of engrafting capability.[393,394] Although some have been implicated in regulation of hematopoiesis, it is likely that others will eventually be shown to modify hematopoietic cell regulation, either directly at the level of HSCs and HPCs, or indirectly at the level of accessory cells (e.g., monocytes/macrophages, lymphocytes, DCs, stromal cells) through their induced production/release of other cytokines and chemokines that affect hematopoiesis.

Prostaglandin E

Although not a protein, PGE is a potent effector molecule and modulator of hematopoiesis and immunity.[395–405] PGEs are eicosanoids (lipid hormone–like signaling molecules) that have been shown to modulate many biologic processes relating to inflammation, such as cellular proliferation, survival, and mobilization, angiogenesis, fever, tumorigenesis, and mature immune cell function. Much of PGEs' ability to augment HSC, HPC, and mature immune cell function is through direct and indirect modulation of cytokine/chemokine secretion and/or function (e.g., IL-1, TNF-α, IL-12, IL-10, IFN-γ, and CXCL2/GROβ) and by regulating the surface expression of cytokine/chemokine receptors (e.g., CXCR4 and IL-1R1). PGE (e.g., PGE_2) has been evaluated in preclinical[404] and clinical settings.[286]

Enzymes, Matrix Metalloproteinases, and Dipeptidylpeptidase 4, as Modifiers of Cytokine/Chemokine Biologic Activities

There is a much-neglected but important role for enzymes in biologically altering proteins that influence hematopoiesis. Matrix metalloproteinases (MMPs) are members of the metzincin group of proteases best known for their ability to collectively degrade a wide variety of components of the ECM and basement membrane.[406,407] The ECM and basement membranes of tissues (e.g., the BM) are often sites for the sequestration of cytokines, chemokines, growth factors, and other bioactive molecules. Thus the ability of MMPs to degrade components of these extracellular structures allows for the release and/or activation of these cytokines/chemokines/growth factors (e.g., TGF-β), increasing their bioavailability and thus allowing for their participation in physiologic functions such as regulating hematopoiesis, immunity, inflammation, angiogenesis, bone remodeling, and tumorigenesis, among others. One pivotal role of MPPs in vivo is to cleave membrane-bound growth factors, chemokines, cytokines, and their receptors from the cell surface, allowing for the shedding of these factors (e.g., several members of the TNF family and IL-6R). Important hematopoietic cytokines and chemokines processed by MMPs include SDF-1, IL-8/CXCL8, IL-1β, and TNF.

Another important modifier of cytokine, chemokine, and growth factor function is the serine protease DPP4. DPP4 truncates proteins at the penultimate amino acid from the N-terminus of the protein.[408–413] This usually occurs when that amino acid is an alanine or proline. However, it can cause this truncation when the penultimate amino acid is also a serine, glycine, or valine but with lower affinity than for alanine or proline. DPP4 exists as a type II membrane protein (CD26) present on many cell types, including HSCs and HPCs, but also exists as a soluble protein due to MMP-mediated cleavage

Figure 11.7 SCHEMATIC REPRESENTATION OF DIPEPTIDYLPEPTIDASE (DPP)4. (A) Membrane-bound DPP4 consists of the C-terminal catalytic domain in which the enzymatic activity of DPP4 occurs, a cysteine-rich region domain in which the fibronectin and adenosine deaminase (ADA) binding sites reside, the glycosylated region domain, a flexible stalk in which matrix metalloproteinases (MMPs) can cleave DPP4, allowing for the shedding of the enzyme off the cell surface, a transmembrane region, and a cytoplasmic domain. DPP4 can transmit signals across cell membranes through its interaction with other membrane proteins. DPP4 can form tetramers with two soluble proteins or two membrane proteins through the ADA and/or fibronectin binding sites and possibly through binding of other protein/extracellular matrix (ECM) components other than fibronectin through specific interaction sites that have yet to be determined. Although DPP4 demonstrates a small amount of enzymatic activity in its monomeric form, experimental evidence suggests that for optimal DPP4 enzymatic activity, DPP4 must be in its more predominant form as a homodimer. (B) Circulating soluble DPP4 contains the same regions as the membrane-bound form of the protein; however, upon cleavage by MMPs at its flexible stalk, soluble DPP4 lacks its transmembrane and cytoplasmic domains. Soluble DPP4 can also initiate intracellular signaling pathways. This function appears to be independent of DPP4's catalytic domain and ADA-binding sites, and its mechanism of action remains poorly understood. (C) For membrane-bound DPP4, DPP4 inhibitors have been shown to inhibit both its ability to cleave substrates by binding to the catalytic site (as is the case with inhibitors such as sitagliptin, diprotin A, tripeptide ILE-PRO-ILE, etc.) and by blocking DPP4's interaction with ECM components and membrane-bound proteins. (D) For soluble DPP4, DPP4 inhibitors have been shown to block its ability to cleave DPP4 substrates, thus preventing the conversion of the substrates to their modified function.

of the cell surface (Fig. 11.7).[406,411] DPP4 shedding is enhanced under hypoxic conditions by specific cell types (i.e., smooth muscle cells), and this increase in DPP4 shedding is associated with increased expression of MMPs. The role of hypoxia in regulating soluble DPP4 concentrations in the BM microenvironment has not been examined.

Current strategies to enhance cord blood transplantation have been described.[414] Also in this strategy is the use of DPP4 inhibition such as sitagliptin.[415–418] Use of sitagliptin for CB transplantation not only resulted in enhanced time to neutrophil recovery but also to lowered GVHD than expected. Sitagliptin also decreased GVHD in patients receiving allogeneic G-CSF–mobilized peripheral blood.[419] A $CD26^+$ subset of polyfunctional $CD4^+$ T cells demonstrated potent antitumor activity.[420] It remains to be determined how these DPP4 inhibitory effects are being mediated, because DPP4 acts on numerous proteins.

There are a number of DPP4 inhibitors.[421] Inhibition of DPP4 on target donor cells[415] or in recipient mice[405] enhances engraftment of mouse BM cells in irradiated recipients. G-CSF and GM-CSF induce upregulation of DPP4, which downregulates SDF-1–induced chemotaxis and negatively regulates GM-CSF, G-CSF, IL-3, and EPO potency in stress conditions. Inhibitors of DPP4 include the orally active small molecule sitagliptin, which was first used to treat type 2 diabetes and subsequently used to enhance the time to engraftment of single unit CB grafts, thereby shortening the time to neutrophil recovery in patients with leukemia and lymphoma undergoing allogeneic stem cell transplantation.[416–418] Other DPP4 inhibitors that have shown efficacy in treating diabetes include saxagliptin, alogliptin, and linagliptin, among others.[410,412] There are many small molecule inhibitors of DPP4, including diprotin A and the tripeptide ILE-PRO-ILE. There are numerous cytokines/chemokines with DPP4-truncation sites or putative DPP4-truncation sites.[421] Examples of CSF proteins with DPP4 truncation sites whose biologic activities that are modified by DPP4 include GM-CSF, G-CSF, IL-3, TPO, and EPO. Of the CSF proteins,[421,422] M-CSF, however, does not have a DPP4 truncation site.[422] It has already been demonstrated that several of the CSF proteins with DPP4 truncation sites, such as GM-CSF, have decreased CSF activity when the protein is truncated by DPP4 as compared with the full-length CSF.[422] In addition, the DPP4-truncated CSF can downmodulate the activity of the full-length CSF.[422] These effects are at least in part due to the truncated CSF binding to these CSF receptors with higher affinity than the full-length CSF. This scenario also occurs with myelosuppressive chemokines, with the DPP4-truncated chemokine having less myelosuppressive activity than that of the full-length chemokine, thus blocking the myelosuppressive effects of the full-length chemokine.[423] Thus inhibition of DPP4 activity can enhance the activity of cytokines/chemokines, by both preventing truncation of these growth regulators and ablating the interfering effects of the truncated growth regulation from binding to and downmodulating the effects of full-length factors at their receptors.

Hence it is important to understand how DPP4 and other enzymes such as MMPs may influence the activity of biologically active proteins with regards to regulation of hematopoiesis. The totality of these interactions and effects have not yet been elucidated. Many studies, especially in clinical trials, assess the serum levels of cytokines/chemokines using enzyme-linked immunosorbent assay (ELISA), yet none of these immunoassays is able to distinguish full-length from truncated proteins. This may thus limit the value of these quantitative protein measurements. Until there are quantitative assays that distinguish full-length from DPP4 or other enzyme-truncated chemokines/cytokines, we cannot be sure how best to interpret such data based upon ELISAs for human cytokines. These limitations can be overcome by use of mass spectrometry to distinguish between a full-length fully functional cytokine and an inactive truncated form.[413]

Microenvironmental Niche and Role of Oxygen Tension in Hematopoiesis

The BM microenvironment is where HSCs and HPCs are mainly nurtured for their proliferation, survival, self-renewal, and differentiation.[424] The BM niche is a complex/dynamic structure encompassing a large number of cell types that act in context of cell-cell interactions and through the constitutive- and/or induced-release of cytokines and chemokines.[424–427] Dysregulated BM niches are associated with abnormalities during many diseases[428,429] such as MPNs, acute myeloid leukemia (AML), and multiple myeloma.[430] For example, microenvironmental cell signaling through notch is associated with development and disease.[431] Manipulating the BM niche accessory cells can also be used to treat/modulate disease severity. For example, it has been postulated that mesenchymal stem/stromal cell therapy may be used as a possible treatment for acute GVHD[427] as well as COVID-19,[432,433] although rigorous proof for use for patients with COVID-19 is currently being evaluated.

A crucial and sometimes ignored or underestimated aspect of the BM niche environment, and the study of cells collected from the BM, as well as the from cord blood and mobilized peripheral blood, for in vitro and ex vivo analysis is that of oxygen tension within the body.[434] The BM is quite hypoxic (1% to 5% oxygen), compared with that of ambient air (~21% oxygen), and even cord blood and adult blood can be relatively hypoxic (<10% oxygen).

Proliferation of HSCs and HPCs ex vivo is known to be more efficient when cells are cultured in an hypoxic environment of approximately 5% oxygen tension, than when these cells are cultured at ambient air O_2.[434–441] However, almost all studies have been based on numbers and activity of HSCs and HPCs first collected and processed in ambient air, regardless of whether the cells were subsequently cultured/studied at ambient air or hypoxic O_2 tension.[442] Hematopoietic cell populations from BM of young adult mice and human cord blood demonstrated a large loss of HSC numbers with an associated increase in HPC numbers within minutes of exposure of these cells to ambient air, via a phenomenon termed extraphysiologic oxygen shock/stress (EPHOSS).[442,443] Loss of HSCs from cells collected and processed in ambient air was due to EPHOSS-induced rapid differentiation of HSCs to HPCs, events not due to HSC death, but mediated through a mitochondrial permeability transition pore (MPTP)-p53-cyclophilin D axis associated with hypoxia inducing factor-1α and the hypoxamir, miR210. This involved rapid increased release of reactive oxygen species (ROS) due to ambient air exposure-induced opening of the MPTP.[442,443] Thus collecting/processing these cells in 3% O_2, such that they were never exposed to ambient air, resulted in increased numbers of phenotypic and functionally engrafting HSCs.[442] Additional studies have demonstrated enhancement in HSC numbers and functions when the cells have been collected and processed at 3% oxygen (= physioxia, in vivo hypoxia conditions).[444–446] Collecting/processing cells at 4°C mimics effects of low O_2, but whether the mechanisms are the same remains to be determined.[447] How cells respond to cytokines in vitro, and also likely in vivo, depends on the oxygen tension the cells are in, both in vitro[434–441] and in vivo.[442–446]

Exosomes/Extracellular Vesicles

Another way that cytokines, chemokines, and other growth-modulating factors can exert their paracrine activities is through their inclusion, along with other intracellular molecules, in extracellular vesicles (EVs). Ectosomes are vesicles that come off the surface of membranes through a process of binding. This includes microvesicles, microparticles, and vesicles which range from 50 nm to 1 µm in diameter. Alternatively, exosomes are EVs that average approximately 100 nm (approximately 40 to 160 nm in diameter; exosomes are endosomal in origin). Most, if not all, cytokines, chemokines, and other growth-modulating proteins/factors can be found encapsulated in EVs, especially in exosomes (see also https://en.wikipedia.org/wiki/Exosome_(vesicle).[448–454] Although the process of EVs/exosomes has been known for many decades, their roles in normal cell regulation and during leukemia, cancer, and other disorders have been especially appreciated in recent years. There are a number of recent reviews on this subject that highlighted their biology, function, biogenesis, and release; how they interact in the hematopoietic environmental niche[448–454]; and their role in leukemia.[454–464] For example, plasma exosomes from patients with AML and during relapse can inhibit colony formation by HPCs (CFU-GM, BFU-E, and CFU-GEMM) from normal donors in a dose-dependent fashion.[464] The exosomes from patients with AML in remission have greatly reduced inhibitory activity on the HPCs from normal donors. Although it is not clear how the combinations of intracellular components in EVs/exosomes manifest their effects, and which such components or combinations of components are actually involved, or exactly how they are involved, this is a rapidly advancing field of investigation. Exosomes from the plasma of patients with AML, as well as from established leukemia cell lines, contained DPP4, and the leukemia exosomes which suppressed HPC colony formation had much higher functional DPP4 activity than that of the exosomes from plasma of normal donors which manifested less or no inhibitory activity.[464] Of interest, the inhibition of DPP4 activity in the AML exosomes greatly or completely decreased the inhibitory activity of the AML exosomes on colony formation of HPC of donors.[464]

Aging in Context of Cell Regulation

Aging is associated with dysregulated hematopoiesis, including that regulated by cytokines, chemokines, and other growth-modulating molecules, and the BM niche.[446,465–468] There has been some evidence that aging-related abnormalities in cytokine/cytokine receptor signaling associated with dysregulated hematopoiesis is made worse upon removal of the aged HSCs and HPCs when processed and analyzed in ambient air, rather than their normal (more hypoxic) microenvironment.446 However, a better understanding of the aging process and hematopoietic cell (HSC, HPC) regulation is required.

Radiation Effects on Hematopoiesis

Radiation not only affects HSCs and HPCs but also accessory, bystander cells.[469–471] This has important implications for hematopoietic cell transplantation. Exactly how and what accessory cells and production of positive and negative growth modulatory factors are influenced remains to be determined.[471]

CONCLUDING THOUGHTS

Although we have learned a great deal about cytokines, ILs, chemokines, and other growth-modulating proteins/factors and their receptor-interactions and how they impact the regulation of HSCs, HPCs, and hematopoiesis, we will likely learn more about their activities and discover new hematopoietic effector molecules in the near future. Studies on effects of growth-modulatory molecules on hematopoiesis require rigorous assays to identify HSCs and HPCs both phenotypically by flow cytometry but more importantly by function. Such methodologies have been described.[472] These to-be-discovered effects will bode well for future preclinical and clinical efforts to treat and cure patients with hematologic and other disorders and malignancies, which in turn will enhance healthcare. One example of this knowledge is the recent report of the use of luspatercept in patients with lower-risk MDS[473] (see also https://en.wikipedia.org/wiki/Luspatercept). Luspatercept is a recombinant fusion protein from human activin R type IIb linked to a protein derived from immunoglobulin G and Actemra (tocilizumab) that blocks IL-6 and is used to treat rheumatoid arthritis (see https://www.verywellhealth.com/actemra-5072997). Hopefully, with increased interest in immune therapies, more applications of our growing knowledge of cytokines, chemokines, and other growth factors can lead to enhancements in clinical efficacy.

CHAPTER 12

ROLE OF CHEMOKINES IN LEUKOCYTE TRAFFICKING

Antal Rot, Elin Hub, Steffen Massberg, Alexander G. Khandoga,
and Ulrich H. von Andrian

The mammalian immune system has evolved to mount multifaceted molecular and cellular microbicidal responses tailored and custom-adapted to eliminate an endless variety of infectious agents and, at the same time, remain tolerant to self-antigens. Accomplishing these tasks requires continuous tightly controlled movement of billions of motile immune cells that roam throughout the body along distinct nonrandom traffic routes from one tissue to another using blood and lymphatic vessels as avenues for rapid access. Migratory pathways characteristic for distinct immune cell subsets are integral parts of their functional make-up determined in the process of cell differentiation and activation. During development in the bone marrow (BM) or thymus, or following stimulation by antigens or pathogen-associated molecules, immune cells acquire the expression of characteristic repertoires of cell surface molecules that enable and restrict their migration to defined tissues and microenvironments. For example, naive lymphocytes largely disregard inflammatory tissue sites, but migrate efficiently into secondary lymphoid organs (SLOs). Conversely, innate immune cells and antigen-experienced lymphocytes can respond to inflammation-induced traffic cues, although some subsets also enter noninflamed lymphoid and nonlymphoid target tissues.[1–4] Notably, not only mature leukocytes but also hematopoietic stem cells (HSCs) and progenitor cells (HPCs), and other rare BM-derived cell subsets recirculate throughout the body.[5–8] The characteristic trafficking routes of leukocyte subpopulations are determined by their expression of cell surface adhesion molecules (see Chapter 15) and chemoattractant receptors. Chemoattractants are produced in target tissues and organs in homeostasis as well as broadest scope of pathologies and signal through cognate receptors on leukocytes to induce their emigration from blood and directed locomotion within the tissues. Leukocyte chemoattractants can be of an exogenous origin; for example, bacterial N-formyl-methionine peptides,[9] tetrapeptides being the most potent and efficacious among them,[10] and many endogenous molecules produced by various host cells, including leukocytes. Endogenous chemoattractants include lipid mediators, e.g., arachidonic acid metabolites, leukotriene B4 in particular[11] or platelet-activating factor,[12] a phospholipid, anaphylatoxic complement fragments C3a, C5a, and C5a-desArg,[13] and most importantly, members of the chemokine family. This chapter discusses chemokines as master navigation signals for leukocyte trafficking and then focuses on specific trafficking pathways that direct leukocyte subsets to distinct target tissues.

CHEMOKINES

Chemokines (a clipping blend of *chemo*tactic cyto*kines*) are critical molecular messengers in the complex cellular communication network used by the immune system. Almost 50 human chemokine genes have been identified to date (Table 12.1).[14–18] The two major subclasses of chemokines are designated CC- or CXC-, reflecting the relative position of the two proximal to the N-terminus canonical cysteines, being either adjacent or separated by a single amino acid, respectively. XCL1 and XCL2, and CX3CL1 represent additional structural chemokine forms with one cysteine and three amino acids between the two canonical cysteines, respectively. CX3CL1 and another chemokine, CXCL16, are associated with a cell membrane via a long spacer sequence and anchored by a transmembrane domain; however, both these chemokines can be cleaved off their stalks and give rise to functional soluble molecules. All other chemokines are secreted proteins of 67 to 127 amino acids. Historically, chemokines have been grouped into functional subfamilies termed *inflammatory* and *homeostatic* chemokines. Former are induced by inflammatory signals and control the recruitment of effector leukocytes in infection, inflammation, tissue injury, and malignancies, whereas those belonging to the latter group navigate leukocytes during hematopoiesis in the BM and in the thymus, during initiation of adaptive immune responses in SLOs and in immune surveillance of healthy peripheral tissues. However, it is now clear that such functional distinction is largely blurred, as many "inflammatory" chemokines are produced under physiologic conditions and the expression of "homeostatic" chemokines is upregulated in inflammation.

Chemokine signals are transmitted through specific cell-surface G protein-coupled receptors (GPCRs) with seven transmembrane domains.[19–23] The human chemokine receptor repertoire identified at present consists of 20 different GPCRs (Table 12.2).[24] The tremendous specificity and plasticity of leukocyte homing and tissue localization is largely determined by the interactions of chemokines with their cognate receptors. Individual leukocyte subsets express highly characteristic fingerprints of chemokine receptors that determine their complex responses to chemokines and define their migratory paths in the body with different receptors playing either nonredundant, combinatorial or overlapping roles.[25] The interactions of individual chemokines and receptors are nonrandom and have been comprehensively characterized. According to new findings, still pending independent confirmation, the last remaining orphan chemokine, CXCL14, known to bind and allosterically modify chemokine receptors, including CXCR4, but not directly signal per se,[26,27] triggers its own GPCR and GPR85.[28] Each chemokine receptor binds either one chemokine or a defined set of them and any individual chemokine can ligate either one unique or several different receptors resulting in some overlap in specificities. However, there are multiple reasons why the apparent "promiscuity" of chemokine-receptor interactions is not a sign of chemokine redundancy and does not reflect a tautology of their signals. First, while the receptor use by different chemokines might overlap, the full spectra of receptors triggered by any particular chemokine are mostly distinct and characteristic for a chemokine, especially within the CC subfamily. Thus, individual chemokines can unmistakably be recognized, albeit in many cases not by one receptor, but by their entire system.[14] Second, messages encoded by individual chemokines that ligate the same receptor are largely unique, because different chemokines have highly disparate binding affinities, interact with distinct receptor moieties and consequently lead to biased signaling, i.e., they induce a dissimilar "texture" of intracellular secondary effectors, activating some and inhibiting others, ultimately resulting in unique spectra of downstream molecular and cellular responses.[29–34] For example, homologous chemokines CCL17 and CCL22 signaling through their cognate receptor CCR4 leads to differential molecular and functional outcomes.[35] CCL19 and CCL21 provide another example of differential, biased signaling through their common receptor CCR7,[36,37] whereby individually or in combination they can induce variations of directed migratory cell responses,

TABLE 12.1 Chemokines and Chemokine Receptors

Chemokine	Chemokine Receptor
CC Family	
CCL1 (I309)	CCR8[a]
CCL2 (MCP-1)	CCR2,[a] CCR5,[a] ACKR1,[b] ACKR2[b]
CCL3 (MIP-1α)	CCR1,[a] CCR5,[a] ACKR2[b]

[a] Agonistic.
[b] "Atypical" receptor.
[c] Antagonistic interaction.
[d] Nonagonist-nonantagonistic interaction.
ACKR, Atypical chemokine receptor; *BCA-1*, B cell chemoattractant 1; *CTACK*, cutaneous T cell-attracting chemokine; *ELC*, Epstein Barr virus-induced molecule 1 ligand chemokine; *ENA*, epithelial-cell-derived neutrophil-activating peptide; *GCP*, granulocyt e chemotactic protein; *GRO*, growth-regulated oncogene; *HCC*, hemofiltrate chemokine; *IP-10*, interferon-inducible protein 10; *I-TAC*, interferon-inducible T-cell alpha chemoattractant; *LARC*, liver and activation-regulated chemokine; *MCP*, monocyte chemoattractant protein; *MDC*, macrophage-derived chemokine; *MEC*, mammary-enriched chemokine; *MIG*, monokine induced by interferon-γ; *MIP*, macrophage inflammatory protein; *SDF-1*, stromal cell-derived factor-1; *SLC*, secondary lymphoid-tissue chemokine; *TARC*, thymus and activation-regulated chemokine; *TECK*, thymus-expressed chemokine.

including chemotaxis, haptotaxis or chemorepulsion.[38,39] Third, chemokines with an apparent overlap of their receptor specificity can behave fundamentally dissimilar due to their differential physicochemical properties, e.g., occurring primarily as soluble versus substrate-bound, as again exemplified by CCL19 and CCL21.[40] Fourth, individual chemokines that ligate the same receptor are produced in vivo in different tissues and/or derive from different cells and/or localize in alternate tissue microenvironments, thus do not act simultaneously but induce distinct, often sequential, steps of leukocyte migratory paths. This was recently shown for two CXCR2 ligands, CXCL1 and CXCL2, which are produced in the vessel wall and by migrating neutrophils, respectively, localize in distinct microanatomical foci thus induce sequential steps of neutrophil emigration.[41] In summary, there are no two chemokines alike and their endless possible combinations allow these structurally homologous signaling molecules to convey most diverse cellular messages acting as building blocks of a universal cell language.[14]

The total number of unique chemokines is further increased by single nucleotide polymorphisms of genes encoding them and their several known spliced variants.[42] Also, practically all chemokines undergo post-translational modifications of their main secreted forms with specific enzymes and protein-modifying agents inducing truncation, degradation, nitration or citrullination of chemokines.[43,44] Many of such modified chemokine isoforms have altered affinity and spectrum of agonistic activities on different receptors and, in some cases, are rendered completely inactive by their processing or gain receptor antagonistic profile.[43] Proteases prominently implicated in processing chemokines include dipeptidyl peptidase IV, also known as CD26, which cleaves two NH2-terminal amino acids of chemokines with alanine or proline at the N-terminal penultimate position, sometimes sequentially, elastase, the ADAM family, as well as matrix metalloproteases (MMPs), a family of more than 20 enzymes with important functions in matrix degradation and multifaceted roles in inflammatory leukocyte recruitment.[44–47] Conversely, some chemokines including CCL14, CCL15, CCL16, and CCL23 are secreted as precursors and their receptor interactive forms are generated upon proteolytic processing by serine proteases and MMPs abundant in the inflammatory tissue environments.[48–50] Also, chemokine processing by glutaminyl cyclase, the modifications to pyroglutamate of their N-terminal amino acids in CCL2 and CX3CL1, is required for protecting these chemokines from proteolysis in vivo and is required for their biological activity.[44,51,52] Further intricacy of chemokine signaling is achieved by the propensity of chemokines to dimerize and oligomerize with chemokine monomers and dimers differentially ligating

TABLE 12.2 Classical Chemokine Receptors

Receptor	Chemokine Ligands	Cell Types
CC Family		
CCR1	CCL3 (MIP-1α), CCL5 (RANTES), CCL7 (MCP-3), CCL8 (MCP-1), CCL13 (MCP-4), CCL14 (HCC1), CCL15 (HCC2, MIP-1δ), CCL23 (MPIF)	T cells, monocytes, eosinophils, basophils
CCR2	CCL2 (MCP-1), CCL7 (MCP-3), CCL-11 (Eotaxin, partial agonist), CCL13 (MCP-4), CCL16 (HCC4)	Monocytes, dendritic cells (immature), memory T cells
CCR3	CCL11 (eotaxin), CCL13 (eotaxin-2), CCL7 (MCP-3), CCL5 (RANTES), CCL8 (MCP-2), CCL13 (MCP-4), CCL15 (MIP-1d), CCL24 (eotaxin-2), CCL26 (eotaxin-3), CCL28 (MEC)	Eosinophils, basophils, mast cells, Th2, platelets
CCR4	CCL17 (TARC), CCL22 (MDC)	T cells (Th2), dendritic cells (mature), basophils, macrophages, platelets
CCR5	CCL2 (MCP-1), CCL3 (MIP-1α), CCL4 (MIP-1β), CCL5 (RANTES), CCL11 (eotaxin), CCL14 (HCC1), CCL16 (HCC4), CCL8 (MCP-2)	T cells, monocytes
CCR6	CCL20 (MIP-3 β, LARC)	T cells (T regulatory and memory), B cells, dendritic cells
CCR7	CCL19 (ELC), CCL21 (SLC)	T cells, dendritic cells (mature), antigen-experienced B cells
CCR8	CCL1 (I309), CCL8 (MCP-2, mouse)	T cells (Th2), dendritic cells
CCR9	CCL25 (TECK)	T cells, IgA^+ plasma cells
CCR10	CCL27 (CTACK), CCL28 (MEC)	T cells
CXC Family		
CXCR1	CXCL8 (interleukin-8), CXCL6 (GCP2)	Neutrophils, monocytes
CXCR2	CXCL8, CXCL1 (GROα), CXCL2 (GROβ), CXCL3 (GROγ), CXCL5 (ENA-78), CXCL6, CXCL7 (NAP-2)	Neutrophils, monocytes, microvascular endothelial cells
CXCR3-A	CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)	Th1 helper cells, mast cells, mesangial cells
CXCR3-B	CXCL4 (PF4), CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)	Microvascular endothelial cells, neoplastic cells
CXCR4	CXCL12 (SDF-1)	Widely expressed
CXCR5	CXCL13 (BCA-1)	B cells, follicular helper T cells (T_{FH})
CXCR6	CXCL16 (SR-PSOX)	$CD8^+$ T cells, natural killer cells, memory $CD4^+$ T cells
CXCR8	CXCL17	Monocytes, T cells, neutrophils, dendritic cells
CX_3C Familiy		
CX_3CR1	CX3CL1 (fractalkine)	Macrophages, NK-cells, endothelial cells, smooth-muscle cells
XC Family		
XCR1	XCL1 (lymphotactin), XCL2	T cells, natural killer cells

BCA-1, B cell chemoattractant 1; *CTACK*, cutaneous T cell-attracting chemokine; *ELC*, Epstein-Barr virus-induced molecule 1 ligand chemokine; *ENA*, epithelial-cell-derived neutrophil-activating peptide; *GCP*, granulocyte chemotactic protein; *GRO*, growth-regulated oncogene; *HCC*, hemofiltrate chemokine; *IP-10*, interferon-inducible protein 10; *I-TAC*, interferon-inducible T-cell alpha chemoattractant; *LARC*, liver and activation-regulated chemokine; *MCP*, monocyte chemoattractant protein; *MDC*, macrophage-derived chemokine; *MEC*, mammary-enriched chemokine; *MIG*, monokine induced by interferon-γ; *MIP*, macrophage inflammatory protein; *SDF-1*, stromal cell-derived factor-1; *SLC*, secondary lymphoid-tissue chemokine; *TARC*, thymus and activation-regulated chemokine; *TECK*, thymus-expressed chemokine.

receptors and causing biased signaling, as has been shown recently for CXCL12.[53] Moreover many, but not all, chemokines form heterodimers within and across their structural sub-family boundaries following a recently mapped pattern of nonrandom specificity.[54] The resultant chemokine heterodimers shift the use of their receptors as compared to the individual monomeric chemokines.[54]

SIGNALING BY CHEMOKINE RECEPTORS

Chemokine receptors, just like other GPCRs, function as allosteric molecular relays where chemokine binding to the extracellular portion modifies the receptor's tertiary structure. This allows the intracellular domain of the engaged receptor to bind to and activate heterotrimeric G proteins. In response, the activated G-proteins exchange GDP for GTP and in the process, dissociate into Gα and Gβγ subunits. Curiously, different chemokine receptors are able to associate with different subsets of Gα subtypes, though any particular functional relevance of such biased signaling is not yet clear.[55] The dissociated Gβγ subunits mediate large parts of chemokine-induced signals by activating different phosphatidylinositol 3-kinase (PI3K) isoforms, leading to the formation of phosphatidyl-3,4,5-triphosphate (PIP_3). PI3K and its product PIP_3 then translocate to the pseudopod at the leading edge of migrating leukocytes, where they colocalize with the small GTPase Rac.[56–59] PIP_3 activates Rac through specific guanine nucleotide exchange factors.[60,61] Rac in turn acts through the downstream effectors p21-activated kinase and the Wiskott-Aldrich protein homologue WAVE, which stimulate actin-related protein 2/3. Together, this process induces focal polymerization, required for the development and forward extension of the pseudopod, a critical step in leukocyte chemotaxis.[62] The importance of PI3K-dependent signaling for leukocyte chemotaxis is evidenced by the lack of migration of myeloid leukocytes to chemokines in mice lacking PI3Kγ[63–68] Notably, though, distinct signaling pathways or at least other PI3K isoforms appear to be involved in the trafficking of immune cells. For example, neutrophil and B-cell migration requires PI3Kδ,[69–72] whereas T-cell chemotaxis is not impaired in PI3K-deficient mice, but depends on the Rac guanine exchange factor DOCK2.[73–75]

Several pathways have been identified that can terminate chemokine signaling through their GPCRs. The Gα subunit possesses an intrinsic GTPase activity to hydrolyze GTP. In a negative-feedback loop, this GTPase activity allows the Gα subunits to reassociate with the Gβγ subunits, thereby restoring the heterotrimeric G protein to its inactive state. In addition, another class of molecules, known as regulators of G protein signaling (RGS), also modulates signaling through chemokine GPCRs. RGS are a large and diverse protein family initially identified as GTPase-activating proteins of heterotrimeric G- protein Gα-subunits.[76,77] At least some RGS can also influence Gα activity through either effector antagonism by competing with effector molecules for GTP-bound Gα-subunits or by acting as guanine nucleotide dissociation inhibitors.[76] To date, over three dozen genes have been identified within the human genome that encode proteins containing an RGS or RGS-like domain. Additionally, chemokine-induced receptor signaling is terminated by specific cytosolic enzymes known as GPCR kinases or GRKs.[78] GRKs are able to rapidly phosphorylate the intracellular domains of the receptors thus, on one hand, abolishing G-protein-mediated signaling and, on the other hand, permitting the association of β-arrestins with the receptors.[79] Such engagement of β-arrestins promotes the internalization of chemokine-triggered GPCRs from the cell membrane into intracellular vesicular compartments with the internalized chemokines targeted for lysosomal degradation and GPCRs either being also degraded or, alternatively, recycled back onto the cell membrane. Thus, pathways that involve GRKs and β-arrestins importantly mediate receptor "desensitization."[79] The activation of Src-family kinases downstream of the chemokine receptors via not yet fully mapped pathways involving G-proteins- and β-arrestins also contribute to the negative regulation of chemokine-induced migratory responses of myeloid cells.[80] In addition to its well-documented role in shutting down chemokine receptor signaling and contributing to receptor desensitization, β-arrestins also play important roles in mediating some of the cellular effects downstream of chemokine receptors by triggering the activation of multiple intracellular molecular signals, thus "redirecting" signaling from G-proteins to the G-protein-independent pathways.[32,81]

Remarkably, the molecular mechanisms involving RGS proteins and GRKs contributing to the "negative regulation" of chemokine signaling through their GPCRs might actually be required for optimal chemokine-induced in vitro and in vivo migratory leukocyte responses and their functions in host defense. A mutation (G184S) in Gαi2 protein abolishes its interactions with RGS proteins, thus allowing it to continuously activate the downstream effectors. Neutrophils of mice with such (G184S) mutation showed enhanced rate baseline locomotion but had reduced chemotactic responses in vitro and defective migratory responses in vivo.[82] Analogously, neutrophils deficient of GRK2, the enzyme dominantly involved in desensitization of their chemotactic migration in response to swarming-inducing autocrine chemoattractants, migrated faster, hence covered larger field areas but were functionally less effective, e.g., in locating and killing bacteria.[83]

ATYPICAL CHEMOKINE RECEPTORS

In addition to GPCRs, most chemokines also bind to one or multiple among the "atypical" chemokine receptors (ACKRs).[84,85] Currently four ACKRs have been included in the nomenclature (Table 12.3), which were shown to bind a broad range of chemokine ligands.[86] It is now clear that at least one additional ACKR exists, pending its inclusion in the systemic nomenclature.[87] Analogously to chemokine GPCRs, ACKRs are serpentine membrane receptors with seven transmembrane domains. However, unlike GPCRs, ACKRs lack or have an altered DRYLAIV consensus motive in the second intracellular loop, which is required for G-protein coupling and signaling through G-proteins. Therefore, upon chemokine binding ACKRs do not trigger signaling events characteristic of GPCRs and cannot mediate cell migration. However, ACKRs internalize chemokines and may target them either into lysosomes or alternatively into transcytotic cellular pathways.[88] ACKRs may also transmit intracellular signals, independently of G-proteins, for example, through triggering biochemical cascades downstream of β-arrestins or affect signaling through classical chemokine GPCRs expressed by the same cell, possibly through receptor heterodimerization or the consumption of secondary signaling molecules. Curiously, ACKRs can heterodimerize with the GPCRs which they share with chemokine ligands, e.g., CXCR4 and ACKR3[89] or do not share any, e.g., CXCR2 and CCRL2,[90] although, despite several reports, the latter might not be a bona fide ACKR as only its chemerin- but not chemokine-binding

TABLE 12.3 **Atypical Chemokine Receptors**

Receptor	Chemokine Ligands	Cell Types
ACKR1	CCL2 (MCP-1), CCL5 (RANTES), CCL7 (MCP-3), CCL8 (MCP-2), CCL11 (eotaxin), CCL13 (MCP-4), CCL14 (HCC1), CCL17 (TARC) CXCL1 (GROα), CXCL2 (GROβ), CXCL3 (GROγ), CXCL5 (ENA-78), CXCL6 (GCP-2), CXCL7 (NAP-2), CXCL8 (IL-8), CXCL11 (I-TAC). CXCL12 (SDF1)	Erythrocytes, venular endothelial cells, cerebellar Purkinje cells and other neurons
ACKR2	CCL2 (MCP-1), CCL3 (MIP-1α), CCL4 (MIP-1β), CCL5 (RANTES), CCL7 (MCP-3), CCL8 (MCP-2), CCL11 (eotaxin), CCL13 (MCP-4), CCL14 (HCC1), CCL17 (TARC), CCL22 (MDC),	Lymphatic endothelial cells, placenta syncytiotrophoblasts, innate-like B cells, marginal zone B cells, dendritic cells, monocytes, tissue-resident mast cells, macrophages
ACKR3	CXCL11 (I-TAC), CXCL12 (SDF-1)	Blood endothelial cells in brain, embryonic and neonatal tissues, marginal zone B cells, plasmablasts
ACKR4	CCL19 (ELC), CCL20 (MIP3 β), CCL21 (SLC), CCL2 (MDC), CCL25 (TECK), CXCL13 (BCA-1)	Lymphatic endothelial cells in collective vessels and lining the ceiling of the LN subcapsular sinus, skin keratinocytes, thymic epithelial cells, endothelial cells in "peri-marginal sinus" of the spleen red pulp
GPR182	CXCL13 (BCA-1), CCL19 (ELC), CCL21 (SLC), CCL25 (TECK),	Microvascular endothelial cells in lungs, bone marrow, LNs, Peyer patches, liver, and spleen

ACKR, Atypical chemokine receptor; *BCA-1*, B cell chemoattractant 1; *CTACK*, cutaneous T cell-attracting chemokine; *ELC*, Epstein-Barr virus-induced molecule 1 ligand chemokine; *ENA*, epithelial-cell-derived neutrophil-activating peptide; *GCP*, granulocyte chemotactic protein; *GRO*, growth-regulated oncogene; *HCC*, hemofiltrate chemokine; *IP-10*, interferon-inducible protein 10; *I-TAC*, interferon-inducible T-cell alpha chemoattractant; *LARC*, liver and activation-regulated chemokine; *LN*, lymph node; *MCP*, monocyte chemoattractant protein; *MDC*, macrophage-derived chemokine; *MEC*, mammary-enriched chemokine; *MIG*, monokine induced by interferon-γ; *MIP*, macrophage inflammatory protein; *SDF-1*, stromal cell-derived factor-1; *SLC*, secondary lymphoid-tissue chemokine; *TARC*, thymus and activation-regulated chemokine; *TECK*, thymus-expressed chemokine.

activity was independently confirmed.[91] Generally, the main role of ACKRs is to determine in which tissue microenvironments chemokines may or may not exert their activities, achieved either through chemokine scavenging or chemokine transport and presentation in salient tissue microenvironments.[84,85] Based on the chemokine-scavenging activity of some ACKRs, it has been postulated that the key role of this group of ACKRs is to counteract chemokine effects by reducing the chemokine availability in the tissues and in the organism as a whole. However, all ACKRs are expressed in discrete and often sparse cellular microenvironments, and they most effectively modify chemokine availability within the microenvironments of their cellular expression; although, of note, ACKRs expressed in tissues can affect the levels of chemokines in plasma,[85,92,93] with broadly variable impact on leukocyte responses.[14,94] Mechanistically, scavenging of chemokines by ACKRs also might buffer chemokine "noise" and keep chemokine concentrations within the range of optimal dissociation constants (K_d) for their cognate GPCRs.[95] Alternatively, by acting as chemokine sinks, ACKRs that are expressed in juxtaposition to the cellular sources of chemokines can facilitate the formation of functional chemokine gradients.[96] Both of such mechanistic outcomes have been suggested for ACKR4, and despite involving chemokine scavenging support the functions of cognate ligands in mediating cell homing into the lymph nodes (LNs) and spleen.[93,96,97]

CHEMOKINE INTERACTION WITH GLYCOSAMINOGLYCANS

In addition to their classical and atypical receptors, chemokines importantly bind to sulfated glycosaminoglycans (GAG) polysaccharides, heparan sulfate, chondroitin sulfate, and dermatan sulfate.[98] GAGs decorate cell membrane proteoglycans on multiple cells, most notably, endothelial cells where they importantly contribute to the function of the apical surface glycocalyx.[99] Extracellular matrices are also rich in GAGs and their immobilization of chemokines allows for the formation of haptotactic, i.e., substrate-immobilized chemokine gradients that facilitate extravascular leukocyte locomotion.[100,101] Such haptotactic gradients also spontaneously develop in vitro as chemokines avidly bind to plastics, and therefore Boyden-type and other in vitro chemotaxis assays measure haptotaxis and not chemotaxis, without recognizing this fact.[102] Chemokine binding to GAGs is characterized by a considerable selectivity on parts of both different GAGs molecules and different chemokines,[103–105] thus facilitating defined patterns of anatomical and microanatomical chemokine localization and availability. Critical involvement of GAGs supporting chemokine functions in vivo is illustrated by abrogated leukocyte homing to LNs[106] and disrupted chemokine-dependent growth and function of the thymus[107] that can be observed in the absence of local heparan sulfate expression. Mechanistically, GAG binding can augment chemokine activities in vitro[108] and in vivo,[109] by protecting them from proteolytic cleavage and promoting their oligomerization,[109–112] or alternatively, in a diametrically opposite scenario, depending on a cellular context, interfere with chemokine binding to GPCRs.[111–113] It has been suggested that trimolecular complexes of GAG-chemokine-GPCRs are not likely to exist, at least not for some chemokines, e.g., CXCL8.[114] If indeed, some chemokines are unable to bind to charged surfaces and GPCRs simultaneously, chemokine "presentation" would entail merely their retention on cells and in matrices and therefore should require chemokine release into solution to enable the subsequent binding to GPCRs.[115] However, this cannot be universally true as CCL21 induces in vitro haptotaxis when firmly substrate-attached, even printed on the surfaces as a stable photo-immobilized gradient.[116] In addition to GAGs, other charged molecules can also specifically bind chemokines. These include anionic phospholipid phosphatidylserine that decorates apoptotic cells, thus allowing for their rapid detection by phagocytes[113] and collagen IV, thus allowing chemokine immobilization around LN high endothelial venules (HEVs).[117]

Apart from inducing leukocyte migration, chemokines play multiple additional roles in health and disease. Several chemokines, including CXCL1, CXCL6, CXCL7, CXCL8, CXCL9, CXCL10, CXCL11, CXCL12, CXCL13, CXCL14, CCL1, CCL19, CCL20, CCL21, CCL25, and CCL28, or their naturally occurring cleaved fragments have been ascribed direct microbicidal activities, albeit to a variable extent and at concentrations orders of magnitude higher than those required for inducing optimal leukocyte migration.[118] Some of these chemokines are generated in infections, and thus might contribute directly to the first line of anti-microbial host defenses. Others, however, are secreted constitutively, e.g., by epithelial cells of exocrine glands and secreted in sweat, saliva, tears, and colostrum and milk,[119–121] thus could play a prophylactic role in infections and in regulating skin and mucosal microbiota balance. Furthermore, chemokines are fundamentally involved in homeostatic brain functions,[122–124] pathophysiology of reproduction and birth,[125] embryogenesis, including the development of heart,[126] brain,[127] and lymphatic vasculature.[128] Furthermore, chemokines mediate angiogenic repair,[129] control hematopoiesis,[126] induce cell survival and apoptosis in leukocytes,[130] and other cells, including tumor cells, etc. Curiously "the mother of all chemokines," CXCL12, is involved in many of such effects outside leukocyte trafficking. As remarkable is the breadth of different chemokine activities, their main and best studied functions involve the regulation of leukocyte trafficking.

In general, leukocyte trafficking can be classified into three distinct patterns of migration: (1) **entry into tissues** from the circulation; (2) **migration within tissues**; and (3) **exit from tissues**. The following sections will discuss each of these steps in leukocyte trafficking.

LEUKOCYTE ENTRY INTO TISSUES

In order to leave the circulation and enter target tissues, leukocytes engage in several sequential steps of adhesion to the endothelial cells, which most often take place in the postcapillary and small venules.[56,131–136] Discrete adhesion steps are mediated by binding interactions of pairs of adhesion receptors and their counter-ligands expressed in trans-geometry by leukocytes and endothelial cells. The initial tethering of leukocytes to the endothelial cell is induced by adhesion molecules, which can rapidly bind their ligands with high tensile strength. Prime initiators of leukocyte tethering are selectins, expressed on leukocytes (L-selectin), endothelial cells (E- and P-selectin) and platelets (P-selectin). Selectins have constitutive optimal affinity for their counter-ligands, sialomucins that are decorated with oligosaccharides related to sialyl-Lewis^x, including P-selectin glycoprotein ligand (PSGL)-1 and the peripheral node addressin (PNAd). Selectin-mediated adhesion bonds that are formed in the bloodstream are transient and do not allow prolonged, firm leukocyte arrest. As tethered leukocytes are pushed along the vessel wall by the blood flow, selectin bonds continuously dissociate at the cells' upstream end and new ones form downstream, resulting in slow rolling motion characteristic for the leukocyte tethering. To undergo firm adhesion, the rolling leukocyte must engage additional adhesion receptors that belong to the integrin family, particularly CD11a/CD18 (LFA-1), CD11b/CD18 (Mac-1) and the α4 integrins, α4β1 (VLA-4), and α4β7. Without exception, individual integrins are expressed by the subsets of leukocytes and their counter-ligands by the endothelial cells.

To efficiently bind their endothelial cell counter-ligands, leukocyte integrins first need to be activated. Such activation is induced by chemoattractant signals that trigger a rapid reversible change in integrin conformation (leading to enhanced ligand binding affinity) and in integrin clustering (enhancing avidity), or both.[20] A subset of chemokines can associate with the luminal surface of microvascular endothelial cells,[137] allowing them to trigger integrin activation and efficiently induce leukocyte arrest, hence designated *arrest chemokines*.[138] The retention of chemokines on the vessel endothelium is mediated by GAGs in the luminal multifunctional glycocalyx,[139] heparan sulfate in particular.[110] Such apical GAG-immobilized chemokine gradients also drive intraluminal crawling of leukocytes,[140] allowing them to find transmigration hotspots, loci optimal for breaching the endothelial barrier, and migration into the extravascular space.[141] Many chemokines are produced by endothelial cells themselves and either secreted immediately or stored in specialized organelles, the Weibel-Palade bodies, and other storage vesicles and upon secondary stimulation released in the process of regulated exocytosis.[142–144] Chemokines that are produced extravascularly can be transported across the endothelial barrier to the luminal surface.[145] This is triggered by chemokine binding to the atypical chemokine receptor ACKR1[88] normally expressed in venular, but not capillary or arterial endothelial cells[146] but upregulated in endothelia of different vascular segments in inflammation. Such chemokine transcytosis by ACKR1 is especially important in microvascular beds characterized by tightest adhesions between EC, e.g., in the brain vasculature.[147] Similar transport mechanisms exist for other tissue-derived chemoattractant as C5a transcytosis across endothelium is accomplished by its atypical receptor C5aR2.[148] However, soluble tissue-derived chemokines, being small proteins, also can freely diffuse from the extravascular space through the endothelial cell junctions into the blood. As a consequence, the chemokine-encoded signals lose their attribution to the sites of their origin and become systemic stimuli in blood.[94] This process is counteracted by ACKR1, which salvages escaping into circulation chemokines by capturing them and presenting them in luminal and junctional membrane microdomains.[41,88] Importantly, chemokine binding to ACKR1, in contrast to other ACKRs, does not lead to chemokine targeting into lysosomes and their degradation.[88] ACKR1 has been initially described on the red blood cells as the Duffy blood group antigen/receptor for chemokines or DARC where it acts as a chemokine sink and reservoir as well as entry receptor of malarial parasite Plasmodium vivax.[149] Erythrocytes are devoid of transcription and translation, hence ACKR1 is expressed already by their precursors, nucleated erythroid cells of the BM, in which it mediates their cell contacts with HSCs and HPCs and thus contributes to the regulation of hematopoiesis.[150] ACKR1 is the most promiscuous of all chemokine receptors but binds its ligands within a very broad spectrum of affinities. Due to differential affinities of individual chemokines and their monomeric versus dimeric forms,[151] chemokines can compete for ACKR1 binding, shifting the equilibria of free and bound chemokines in the tissues and in plasma.[152]

Chemokines signaling via the Gα_i subfamily of large heterotrimeric G proteins can be inhibited by pertussis toxin (PTX). Consequently, intravital microscopy studies have shown that PTX-treated lymphocytes undergo normal tethering and rolling interactions in HEV in LNs and Peyer patches (PPs) but are unable to undergo integrin-dependent firm arrest. Chemokine receptor activation precipitates a cascade of intracellular signaling and adapter proteins, including Kindlin-3 and RAP-RAPL, that are involved in the so-called inside-out signaling that results in integrin activation. Modifications at the cytoplasmic tails of the integrin α and β chains are critical to regulating leukocyte adhesion to integrin ligands, such as the binding and spreading of neutrophils on intercellular cell adhesion molecule-1 (ICAM-1) and the complement C3 activation product, iC3b.[153] Surprisingly, some chemokines, e.g., CX3CL1 and CXCL12 can directly bind to the alternative bindings sites of leukocyte integrins αvβ3 and α4β1 and allosterically activate them without signaling through their respective GPCRs.[154,155] Once firmly adherent, leukocytes rapidly polarize and slowly migrate within the vessel in random directions.[156–158] The intralumenal crawling is thought to be essential to enable leukocytes to find exit points within the vessel through which they can leave the vasculature.[56] A subset of monocytes crawl within normal microvessels under steady-state conditions.[133,159,160] These patrolling monocytes are poised to provide immune surveillance of the endothelial cell surfaces and clear the intravascular debris[160] but may also enter the extravascular space in response to damage and infection. Once emigrated, some mononuclear cells may differentiate into macrophages or dendritic cells. In some tissues and organs, intestine, monocyte emigration contributes throughout life to the replenishing of the resident macrophage pool.[159,161,162] In other tissues, macrophage and dendritic cell precursors home only during the embryonic period from either the liver or yolk sack and the resident mature cells proliferate in situ to give rise to their progeny.[163,164]

The interactions between β2-integrins, LFA-1, and Mac-1, with endothelial ICAMs are required for intravascular adhesion and crawling. However, the specificity of these interactions differs between different leukocytes, e.g., neutrophils and monocytes.[156,159] Neutrophil luminal crawling is mainly mediated by Mac-1,[156] whereas monocytes and T cells use LFA-1,[1,159] Recent studies using blocking antibodies against Mac-1 and LFA-1 showed that crawling patterns of monocytes and neutrophils differ at steady-state versus inflammatory conditions; both LFA-1 and Mac-1 contribute to monocyte crawling; however, the LFA-1–dependent crawling in unstimulated venules becomes Mac-1 dependent upon inflammation. By contrast, Mac-1 alone is responsible for neutrophil crawling in both unstimulated and cytokine-stimulated venules.[165] This indicates that differences in monocyte and neutrophil crawling behavior result from involvement of different β2 integrins and consequently affect the next step of the leukocyte migration cascade, the transendothelial migration.

The transendothelial migration or diapedesis is a critical event allowing leukocytes to cross the vascular wall and enter their target tissue. Two main routes of leukocyte diapedesis have been observed: a paracellular route that dominates most extravasation processes and a transcellular route, reported for neutrophils and T cells.[166–172] Both routes involve the action of apical and junctional endothelial intercellular adhesion molecule-1 (ICAM-1) and, at least in some settings, also vascular cell adhesion molecule-1 (VCAM-1). Under inflammatory conditions, additional junctional endothelial ligands such as PECAM-1, VE-cadherin, ESAM, CD99, CD99L2, and junctional adhesion molecules (JAMs) can contribute to leukocyte diapedesis.[167,173–179] Different subsets of leukocytes use variations on these molecular mechanisms to emigrate into the tissues.[180]

After penetration of the endothelial barrier, leukocytes may move further within the interstitium towards their target destinations in the tissue. This locomotion is considered to reflect in vivo chemotaxis, increased rate directed cell locomotion driven by the putative gradients of chemoattractants.[181,182] Several signaling pathways have been proposed to be involved in this gradient-driven process, the most predominant being the PI3K pathway.[64] Thereby leukocytes use an "internal compass" for sensing the direction of chemotactic gradients, and undergo polarization characterized by the formation of lamellipodia at the leading edge of the cell and an uropod at the trailing edge.[183,184] Chemokines released by a broad range of tissue cells, epithelial cells, mast cells, smooth muscle cells, fibroblasts, myocytes, and tissue-resident immune cells may form gradients and mediate the leukocyte chemotaxis in the interstitium. In this context, the spatiotemporal formation of chemokine gradients in the interstitial tissue may be supported by GAGs, which immobilize chemokines and, thus, determine the position and temporal persistence of chemokine gradients.[185,186] It has been shown that immobilized, substrate-bound chemokines are effective in inducing directed leukocyte migration, haptotaxis.[102] It has also been suggested that efficient development of chemokine gradients requires, in addition to the free diffusion of chemokines from their cellular sources, also scavenging by their ACKRs expressed by cells in apposition to chemokine sources.[96] Additionally, responding leukocytes may also scavenge chemokines, thus participating in the formation of their functional gradients.[187] Leukocytes moving within the interstitial tissue receive signals from neighboring cells as well as from the extracellular matrix, activate intracellular processes, release inflammatory mediators, and upregulate adhesion molecules and release enzymes.[188] Neutrophils display enhanced expression of β1-integrins upon transmigration into the tissues, and integrins contribute but are not absolutely required for interstitial leukocyte migration. Importantly, the involvement of integrins is different in 2D versus 3D settings.[189] Integrins are dispensable for migration through the 3D tissue fiber networks that confine and mechanically anchor cells from all sides so that they intercalate alongside and perpendicular to tissue structures as shown for integrin-deficient DCs. However, migration on 2D surfaces was shown to be integrin-dependent.[189]

All consecutively occurring steps of (1) leukocyte tethering and rolling, (2) exposure to a chemotactic stimulus, (3) firm arrest, (4) post-adhesive strengthening and intralumenal crawling, (5) diapedesis, and (6) interstitial migration are essential for leukocytes to migrate to sites of inflammation. Accordingly, genetic defects in any of the molecules involved in either step lead to insufficient host defenses. Patients with leukocyte adhesion deficiency (LAD) syndrome, may have a genetic defect in β2 integrins (type 1) or in fucosylated selectin ligands (type 2) and neutrophils either cannot stop or cannot roll, respectively. LAD syndrome is characterized by marked leukocytosis and frequent and severe soft-tissue infections.[190–192] Another LAD variant referred to as LAD3 is caused by mutations affecting the FERMT3 gene that encodes focal adhesion protein kindlin-3, resulting either in the lack of this protein or its defective function in activating leukocyte and platelet integrins.[193]

Chemokine Control of Lymphocyte Homing to Secondary Lymphoid Organs

Migration of blood-borne lymphocytes to SLOs is the best-characterized example of leukocyte trafficking from the circulation into distinct target tissues.[2,4,194–199] Lymphocyte subsets constantly survey SLOs, which include the spleen, tonsils, appendix, PPs, and LNs. Such homing allows lymphocytes to encounter antigen that may pose a threat to the organism. Antigens are collected and presented to T cells by dendritic cells, in conjunction with signals by costimulatory molecules and cytokines. In contrast to the spleen, where the molecular mechanisms of leukocyte homing still are not entirely clear and differ from all other lymphoid organs,[93,200] the rules which govern homing of immune cells to LNs are well understood. Mature dendritic cells, that have acquired antigen in peripheral tissues, and some memory cells reach the LNs through afferent lymph vessels.[201–203] In contrast, circulating in blood T and B lymphocytes gain access to LNs through specialized postcapillary microvessels lined with cuboid endothelial cells that are known as *high endothelial venules* (HEVs).[204–207] HEV are also present in other SLOs and appear in tertiary lymphoid organs (TLOs) induced in multiple tissues by various pathologies, most notably autoimmunity[208] and cancer.[209] HEV in SLOs and TLOs express distinct patterns of trafficking molecules to serve as tethering platforms for defined subsets of lymphocytes. For example, HEV in LNs express PNAd, whereas HEV in PPs express mucosal addressin-cell adhesion molecule (MAdCAM-1). Other mucosa-associated lymphoid organs, such as mesenteric LNs express both MAdCAM-1 and PNAd. Although T and B lymphocytes are recruited by similar multistep cascades to home to SLOs, the roles of individual traffic molecules are not necessarily identical, even when both subsets interact with the same microvessel.[2]

The first step in the homing cascade in LNs is mediated by L-selectin/CD62L expressed on all lymphocytes, except effector/memory cells. PNAd, an O-linked sulfated core 1 carbohydrate moiety that is exclusively found in HEV, is the major endothelial L-selectin ligand.[210–214] Binding of L-selectin to PNAd initiates lymphocyte rolling in HEV and slows down and marginates the free-flowing lymphocytes.[2,136,213] While the L-selectin-PNAd interaction is required, it is not by itself sufficient to promote firm leukocyte adhesion. The subsequent firm arrest of rolling T and B lymphocytes is mediated by the α4β1 integrin, β2-integrin CD11a/CD18 (LFA-1), CD11b/CD18 (MAC-1) and β7-integrin, which bind intercellular adhesion molecules (ICAM), in particular ICAM-1 and ICAM-2, VCAM-1 or MAdCAM-1 on high endothelial cells.[213–218]

Chemokines that are presented on the apical side of HEV function as triggers of integrin activation.[219,220] On naive T cells, integrin activation is primarily mediated by CCL21 (previously known as SLC, TCA4, exodus 2 or 6-C-kine), which is constitutively expressed and secreted by HEV. The secreted chemokine is noncovalently bound to GAGs on the surface of HEV. Here, it activates rolling lymphocytes through binding to CCR7, which is expressed on naive B and T cells. Another CCR7 ligand, CCL19 (previously termed ELC or MIP3β), also supports T-cell homing to LNs.[220] CCL19 is not expressed by LN high endothelial cells themselves. However, CCL19 and other chemokines may be released by extravascular cells in LNs or in tissues that discharge lymph to a local LNs and readily trancytoses to the luminal aspect of HEV. Correspondingly, chemokines, including CCL2, CCL19, and CCL21, injected under the skin of mice accumulate on the luminal surface of the HEV in draining LNs, where they promote integrin activation on rolling leukocytes bearing the cognate receptors.[221–223] In this context, endothelial heparan sulfate has been shown to be essential for controlling chemokine presentation on the endothelium and thereby for recruitment of lymphocytes and dendritic cells to LNs.[106]

B cells use largely the same trafficking molecules as naive T cells to home to LNs. However, B cell-HEV interactions are only moderately affected by the absence of CCR7 or its ligands.[224] Correspondingly, LNs of mice lacking CCR7 contain few T cells, while the B cell compartment (and the memory T-cell compartment) is less affected.[225,226] Similar observations were made in *plt/plt* mice, which have a spontaneous genetic defect resulting in deletion of CCL19 and the HEV-expressed form of CCL21 (mice, unlike humans, have a second *ccl21* gene that is only expressed in lymph vessels of peripheral tissues), demonstrating that B cells are not absolutely dependent on CCR7 to adhere to HEV.[224] In fact, rolling B cells can be induced to arrest in HEVs by either CCR7 agonists or by CXCL12 (previously called stromal cell-derived factor [SDF-1]α), the ligand for CXCR4.[227] An additional chemokine pathway involving CXCL13 (also called BLC) and its receptor CXCR5 has also been implicated in B cell homing to secondary lymphoid tissues.[228] Of note, although B cells encounter several distinct integrin-activation signals in HEV, B cell homing to LNs is nonetheless less efficient than that of T cells. A likely reason is that the B cells express only approximately half the number of L-selectin molecules expressed on T cells, which greatly affects their ability to initiate the adhesion cascade in HEV.[207,229]

The requirement for a sequence of distinct molecular steps that each leukocyte must undergo to arrest within microvessels, explains why only certain leukocyte subsets gain readily access to lymphoid tissues, while others are largely excluded. Granulocytes, for example, express LFA-1 and L-selectin, but not CCR7. Consequently, although granulocytes can roll in HEV (via L-selectin), these leukocytes do not perceive an integrin-activating stimulus and, therefore, fail to massively accumulate in LNs or PPs. It has been clear for some time that alternative to CCL19/CCL21-CCR7 chemokine-receptor pathways can also be involved in leukocyte homing in HEVs,[223,230] thus some neutrophils can traverse HEVs, in low numbers under physiological conditions and in dramatically increased numbers in infection.[231] Mature dendritic cells also express CCR7 and CD11a/CD18, but not L-selectin. These cells when in circulation are incapable of rolling in HEV, and they fail to home to noninflamed LNs from the blood (although mature dendritic cells readily access LNs via afferent lymph). Hence, the GPCR-mediated integration activation step is critical for imparting specificity to the process of lymphocyte homing to LNs.

In HEVs of PPs, similar homing mechanisms are encountered as described above for LNs. However, the levels of L-selectin ligands (which are immunologically distinct from PNAd) expressed by HEV in PPs are considerably lower when compared with LNs.[232,233] As a result, L-selectin itself is not sufficient to initiate a successful homing cascade for most lymphocytes in PPs.[232] Indeed, HEV in PPs (and also in mucosa-associated LNs) express additionally MAdCAM-1, a ligand for the α4β7 integrin.[232–234] The α4β7 heterodimer, which comprises an α4 integrin chain (CD49d) linked to the β7 integrin chain, is expressed at low levels by naive T and B cells and is required for the successful homing of these cells in PP HEV.[232] Following formation of an initial L-selectin-dependent tether, the α4β7-MAdCAM-1 pathway stabilizes and slows the rolling lymphocytes without requiring chemokine activation. Once a chemokine signal has been transmitted, both α4β7 and LFA-1 become activated and jointly mediate firm cell arrest on the endothelium.[232]

Of note, α4β7 is strongly upregulated on gut-homing effector/memory lymphocytes, but completely absent on skin-homing memory T and B cells; these differential levels of α4β7 integrin expression allow certain antigen-experienced lymphocyte subsets to acquire tissue selectivity.[235] The mechanisms underlying this specificity and plasticity of lymphocyte homing will be addressed below. Like in LNs, chemokines are essentially involved in promoting integrin activation and allowing firm lymphocyte arrest in HEV of PPs. Thus, CXCR4, CXCR5, and CCR7 have been implicated in B cell homing, while CCR7 seems exclusively responsible for T-cell homing. Interestingly, while T and B cells are recruited across the same HEV in LNs, there is segmental segregation of T and B cell recruitment in PPs. HEV supporting B cell accumulation in PPs are concentrated in or near B follicles and present CXCL13, but not CCL21, whereas T cells preferentially accumulate in interfollicular HEV (i.e., within the T-cell area), which express high levels of CCL21, but not CXCL13.

Trafficking of Leukocytes From Blood Into Nonlymphoid Tissues

As outlined above, naive and subsets of memory lymphocytes migrate most efficiently to SLOs. Both innate immune cells and multiple subsets of lymphocytes can respond to inflammatory and/or activation signals by modulating the expression and/or activity of traffic molecules in a way that allows them to migrate to nonlymphoid tissues (4). For example, in response to an inflammatory stimulus, granulocytes, including neutrophils, eosinophils and basophils, are rapidly recruited to the affected site and provide the first line of defense. Thereafter, additional immune cells, including monocytes, dendritic cells, and effector as well as memory lymphocytes, may be recruited. Essentially, all these different recruitment events depend on distinct multistep adhesion cascades.

Many of the traffic molecules required for the access of inflammation-seeking leukocytes to nonlymphoid tissues are shared by their different subsets. The key receptors that initiate capture and mediate rolling of neutrophils, monocytes, natural killer cells, eosinophils, and effector T and B cells at peripheral sites of injury and inflammation are the three selectins, the leukocyte-expressed L-selectin and P- and E-selectin on stimulated endothelial cells.[236–240] In addition, interactions between leukocytes involving PSGL-1 and L-selectin can also support the accumulation of immune cells in inflamed tissues.[239,241–243] Subsequent to rolling firm arrest of leukocytes in nonlymphoid tissues involves integrins, including CD11a/CD18 (and its ligand ICAM-1 and possibly also ICAM-2), VLA-4 (and its ligand VCAM-1), as well as CD11b/CD18 (and its ligand ICAM-1).[1,56,244] As discussed above for lymphoid tissues, chemoattractants, including chemokines and other GPCR agonists, such as formyl peptides, complement fragment C5a and lipid mediators (e.g., PAF and LTB4), contribute essential integrin-activation signals for leukocytes at sites of inflammation. The molecular diversity of chemoattractants and their restricted temporal and spatial expression patterns combined with leukocyte-subset specific fingerprints of chemoattractant receptor expression provide a crucial mechanism for the fine-tuning of migratory cellular responses.[136,245,246]

In contrast, the migratory properties acquired by T and B lymphocytes in response to activation are diverse depending on the strength, the quality, and the context of the antigenic stimulus.[235] Specifically, antigen stimulation of naive lymphocytes results in generating effector and memory cells that express specific repertoires of trafficking molecules that guide them back to tissues containing the stimulatory antigen.[247–249] Thus, a cutaneous challenge generates preferentially a skin-tropic memory response, whereas orally ingested antigens induce preferentially gut-homing effector and memory cells. In addition to presenting antigen, dendritic cells in different lymphoid organs are endowed with information characteristic for the tissue in which the antigen was obtained. Dendritic cells in mucosa-associated lymphoid tissues, but not other lymphoid organs, possess the enzymatic machinery to synthesize retinoic acid (RA) from vitamin A.[250] Exposure of activated T cells to RA induces the expression of gut-homing receptors (i.e., α4β7 and CCR9) and suppresses skin-homing molecules.[248,251] In the absence of RA, T-cell stimulation induces few or no gut-homing molecules, but instead promotes the expression of P- and E-selectin ligands as well as CCR4, which are needed for homing to the skin. Additionally, when activated T cells are exposed to IL-12 and high levels of vitamin D3, which is physiologically induced by sunlight in the skin, they upregulate CCR10, the receptor for the epidermal chemokine CCL27.[252] This organ-specific information can reprogram and "imprint" the tissue-tropic memory cells as they differentiate from naive lymphocytes.[249]

Like T cells, B-cell subsets also express homing receptors that permit their selective trafficking to specific tissues. For example, distinct B cell subsets produce the immunoglobulin isotype IgA that is present in secreted body fluids, including tears, breast milk, and mucus. IgA$^+$ B cells are characterized by their expression of CCR10.[253,254] The ligand for CCR10, MEC/CCL28, is expressed predominantly in mucosal tissues that secrete IgA.[255] Hence, CCR10 may function as a homing receptor that allows IgA-secreting B cells to migrate to tissues where IgA is required. A large subset among the IgA secreting B cells are those in the small intestine, which in addition to CCR10 express the gut-homing receptors, α4β7 and CCR9. When naive B cells are activated in the presence of intestinal dendritic cells, they upregulate not only these two traffic receptors, but also undergo class-switching to IgA. This imprinting effect is dependent upon RA, which is sufficient to induce gut-homing receptors, but must be combined with dendritic cell-derived IL-5 or IL-6 to promote IgA class-switching.[251] More than 50 different subtypes of lymphocytes have been characterized in human blood and it is likely that multiple similar associations between homing receptors, immunological effector function, and tissue specificity will be revealed in the future.

Migration of Hematopoietic Stem Cells to the Bone Marrow and Mobilization in the Niche

The BM is the principal site of hematopoiesis in the adult body. Correspondingly, most HSCs are lodged in the BM cavity. Within the BM, maintenance of HSCs and regulation of their self-renewal and differentiation is thought to depend on the specific microenvironment, which has historically been termed "stem cell niche."[7,256–259] The central role of stem cell niches for HSC function has been recognized with the discovery that *Sl/Sl*^{d} (steel-Dickie) mice bearing a mutation in the gene encoding membrane-bound stem-cell factor (SCF, also known as KIT ligand) show failure of BM HSC maintenance.[260] However, the exact localization and the composition of BM HSC niches and the molecular crosstalk that controls the retention of HSC within the niches are the subject of intense ongoing research.[150,261–264]

Notably though, not all HSCs reside within the BM. In fact, it has been known for almost four decades that a small number of hematopoietic precursors are also present in peripheral blood.[265–268] Blood-borne HSCs continuously migrate back to the BM, presumably to fill any vacant stem cell niches.[268] Although the physiological relevance of blood-borne HSCs remains to be determined, and the magnitude might be limited, the intrinsic capacity of HSCs to home to the BM compartment is the prerequisite for successful clinical BM and stem cell transplantation. Homing of HSCs to BM is a rapid process, since IV-injected murine and human progenitors are quickly cleared from the recipient circulation.[268–270] Like mature lymphocytes, HSCs and HPCs interact through a multistep adhesion cascade with BM microvessels.[6,270–274] Initially, HPCs tether and roll along BM microvessels.[275,276] This process involves α4β7 integrin on HSC/HPC, which binds VCAM-1, as well as E- and P-selectin on BM sinusoidal endothelial cells, which bind α (1–3)-fucosylated ligands including CD44 and PSGL-1 on the surface of HPCs.[270] The subsequent firm arrest is mediated by activated α4β1 and VCAM-1, which is constitutively expressed in BM sinusoids. In addition to α4 β1 integrin, the integrins α4β7, α5β1, and α6β1, CD44 and JAM-B have recently been implicated in HSC homing to the BM.[274,277–280] Integrin-mediated adhesion is important for HSPC movement not only in adulthood, but also during embryogenesis. Thus, HSPCs in the yolk sac, AGM, and placenta express CD41 (GPIIb integrin encoded by the gene *Itga2b*). Expression gradually decreases during development, and adult HSPCs express little or no CD41.[6,281] In addition to CD41, β1 integrins tune the migration of fetal HSPCs. The use of chimeric mice generated with β1-integrin-deficient fetal HSPCs has revealed that fetal HSPCs lacking β1 integrins form and differentiate but they cannot colonize the FL, suggesting an essential role of β1 integrins in fetal HSPC trafficking. The role of the ß2-integrins LFA-1 (CD11a/CD18) and MAC-1 (CD11b/CD18) is controversially discussed. Although some studies have reported their involvement in HSPC retention,[282,283] others have indicated that the effect of β2 integrins becomes apparent only in synergy with α4β1.[284]

The chemokine CXCL12, the ligand for CXCR4 expressed by most hematopoietic cells including HSCs, is thought to play a pivotal role in BM homing of HSC. BM endothelial cells (in addition to immature osteoblasts and other stromal cells) constitutively express and secrete CXCL12. However, alternate pathways appear to exist since fetal liver-derived mouse HSCs home to the BM of adult recipients independent of CXCR4[285] and adult HSCs treated with a CXCR4 antagonist are still able to home sufficiently to the BM.[286] This indicates that HSCs may use different receptors and/or respond to distinct integrin-activation signals.

Of note, the CXCL12/CXCR4 axis is not only involved in the homing process of HSCs to the BM, but (among others) has also been linked to the retention of HSCs within stem cell niches and to the regulation of the maturation of more committed HPCs (in particular B cell progenitor cells) and PMNs.[287–292] Correspondingly, disruption of the CXCL12/CXCR4 pathway leads to release of HPCs and other BM cells into the peripheral blood.[293,294] HPCs lacking CXCR4 accumulate in the circulation and fail to undergo normal lymphopoiesis and myelopoiesis, most likely because the cells do not receive the required maturation signals. Interestingly, upregulation of metalloproteinases (see above), which cleave and inactivate CXCR4 and CXCL12, has recently been implicated in HSC mobilization.[295–298] Mechanisms that modulate the CXCR4/CXCL12 axis are also thought to play a role in the coordinated mobilization of HPCs in response to cytokines that are used for this purpose in clinical practice.[299] Rare autosomal dominant truncations of ten or more nucleotides that encode the C- terminal intracellular domain of human *CXCR4* result in a constitutively signaling CXCR4 and manifest in the WHIM syndrome (*W*arts, *H*ypogammaglobulinemia, *I*mmunodeficiency, and *M*yelokathexis).[300] Recently, described promising WHIM therapy involves chronic administration of the CXCR4 antagonist plerixafor, resulting in amelioration of the main symptoms, including disease-associated myelofibrosis, panleukopenia, anemia, and thrombocytopenia and the reduction of the papillomavirus-associated warts and carcinoma burden and frequency of other infections.[301]

In addition to the CXCL12, the egress from BM niches has been recently shown to be critically dependent on the signals provided by the nervous system. The UDP-galactose ceramide galactosyltransferase-deficient Cgt(-/-) mice exhibiting aberrant nerve conduction are characterized by absence of HSPC egress from BM following granulocyte colony-stimulating factor (G-CSF) or fucoidan administration.[302] Interestingly, norepinephrine (NE) signaling controlled bone CXCL12 downregulation and HSPC mobilization, whereas administration of a beta(2) adrenergic agonist enhanced HSPC mobilization. Therefore, the sympathetic nervous system regulates the attraction of stem cells to their niche via transduction of circadian information from the central pacemaker in the brain, the suprachiasmatic nucleus, to the BM microenvironment.[303] Recent data show that circadian regulation is regulated by beta-2 and beta-3 adrenergic receptors (beta-AR) expressed on HSCs, osteoblasts, and mesenchymal stem/progenitor cells. Moreover, beta(2)- and beta(3)-ARs have specific roles in stromal cells and cooperate during progenitor mobilization.[304] Whereas activation of beta(3)-AR downregulates Cxcl12, beta(2)-AR stimulation induces clock gene expression.[304] In addition, double deficiency in beta(2)- and beta(3)-ARs compromises enforced progenitor mobilization from the BM. For the clinical settings, the timing of stem cell harvest or infusion may influence the yield or engraftment, respectively, and may result in better therapeutic outcomes.[303]

Curiously, the paradigm of BM-derived hematopoietic cells entering blood to redistribute into the tissues is not absolute. Recent findings show that specialized shortcut channels between BM and dura mater of the meninges that surrounds the brain and spinal cord allow the resident in dura myeloid cells and B cells to be replenished directly from the scull- and vertebral BM without the cells ever entering systemic circulation.[305,306] Moreover, the inflammatory cell infiltrates into the brain and spinal cord in injury, experimental autoimmune encephalomyelitis, and the optic nerve crush model are also derived locally from the skull BM.[305] It is not clear if similar direct shortcuts from BM to surrounding tissues exist also in other anatomical locations.

LEUKOCYTE MIGRATION WITHIN TISSUES

Trafficking Patterns of Lymphocytes

After lymphocytes gain access to a tissue, they are able to migrate further to defined functional sites within. As discussed above, homing typically requires that the blood-borne leukocyte completes a complex tissue- and subset-specific multistep adhesion cascade with a possible exception for spleen where most blood-borne lymphocytes appear to leave the circulation in the absence of conventional traffic molecules. However, chemokines are essential in all lymphoid organs, including the spleen, to guide the newly arrived lymphocytes to their proper position within the organ.

Multiphoton intravital microscopy was used as a tool to decipher the mechanisms that control the extravascular traffic patterns of homed lymphocytes within lymphoid and nonlymphoid tissues.[307–315] For example, imaging experiments have shown that T cells that have entered a LN move incessantly within the paracortex (T-cell area). Here, they query the resident dendritic cells for the presence of antigens that activate their T-cell receptor (TCR). B cells that home to LNs migrate to the more superficial B-cell-rich follicles, where they may detect antigens presented by follicular dendritic cells (FDC). Activated B cells that encounter antigens then move to the margins of the B- and T-cell zones.[310] Here, they can receive help from antigen-specific CD4 T cells. Analogous specific microenvironments for T and B cells exist also in the other lymphoid tissues. In contrast to the step of trans-endothelial lymphocyte egress from blood, their crawling on the luminal endothelial cell surface preceding emigration,[316] as well as their chemokine-driven migration in the tissue, do not necessarily require integrins.[189,317] However, integrins contribute to the extravascular leukocyte motility, in either norm, or inflammation,[318] to T-cell migration in LNs, though acting not necessarily downstream of chemokine signaling but independently and in parallel to it. This suggests the involvement of differential molecular pathways downstream of chemokine receptors involved in leukocyte emigration versus their tissue migration.[319]

Migration of T Cells to T Zones Within Secondary Lymphoid Organs

After homing to SLOs, T cells migrate within the T zones. They engage in highly motile ameboid movement (average speed ~12 μm/min) and undergo multiple brief encounters with resident dendritic cells.[320–322] In this context, the fibroblastic reticular cell (FRC) network regulates naive T-cell access to the paracortex and also defines the limits of T-cell movement within this domain.[323,324] As a consequence of high velocity of T-cell motility, it has been estimated that every dendritic cell in a LN touches as many as 5000 naive T cells within one hour. When T cells encounter a specific antigen, they progressively decrease their motility, become activated and form long-lasting stable conjugates with DCs. Finally, antigen-experienced

T cells start to proliferate and resume their rapid migration while contacting DC only briefly.[322,325] The positioning and high motility of T cells in the T-cell area is dependent on CCR7 and its ligands CCL19 and CCL21.[195,225,226,307,326,327] Both ligands are abundantly expressed in T zones by the radiation-resistant stromal cells. Notably, ectopic expression of CCL21 induces the formation of LN-like structures in nonlymphoid tissues, e.g., the pancreas of mice.[328] The expression of CCL19 and CCL21, but also of CXCL13, a B-cell chemoattractant (see below), by stromal cells is strongly dependent on the cytokine lymphotoxin (LT)-α1β2 heterotrimers signaling via LT β receptor.[329–331] Correspondingly, mice deficient in LT have no morphologically detectable LNs or PPs.[332] Also, on one hand, CCL21 and CXCL13 have been shown to be transiently downregulated by a mechanism downstream of the cytokine interferon-γ altering lymphocyte and dendritic cell recruitment with possible consequences of mitigated T-cell responses to a subsequent second pathogen.[333,334] On the other hand, interferon-γ-inducible chemokines CXCL9 and CXCL10 produced in the LN by stromal cells and DCs, respectively, signal through CXCR3 on $CD4^+$ T helper 1 cells to optimize their LN positioning within interfollicular and medullary zones and promote their interaction with DCs and, consequently, effective differentiation.[335] Analogously, the same pair of chemokine ligands signaling through CXCR3 on CD8 T cells was shown to be responsible for their effector lineage differentiation and correlated with the segregation of CD8 memory and effectors at the LN periphery.[336] CD8 T cells that lacked CXCR3 remained in the LN center and differentiated into stem-like memory cell precursors.[337]

Positioning of B Cells Within Secondary Lymphoid Organs

Similar to T cells, B cells enter SLO from the blood to search for their specific antigens.[338] Also, the homing and entry of B cells into SLO such as the LNs and PPs depends on chemokine/receptor interactions that finally result in firm adhesion of integrins on the surface of HEV. This adherence is followed by movement into lymphoid tissue.[227,333,339,340] After entering SLO, the naive B cells travel to B-cell-rich areas, the B-cell follicles. This migration depends on the presence of CXCR5 on the surfaces of B cells and the localized expression of CXCL13 by follicular stromal cells.[194,331,340] Follicular B cells are also highly motile migrating on a network of FDCs, a process that is thought to be necessary to ensure optimal surveillance of the FDC for surface-displayed antigens. After a period of random migration within follicles, B cells that have not encountered a cognate antigen return to the circulation via the lymph or, in case of the spleen, via the blood. In contrast, B cells that become stimulated by antigen relocate to the B-T boundary area to solicit help from T cells, which is necessary for further differentiation. To achieve this repositioning, activated B cells rapidly upregulate CCR7. This permits their chemotaxis toward CCR7 ligands expressed in the T-cell-rich zones of the SLOs.[310] Real-time imaging has been performed to further characterize the timing of this relocalization process. Antigen-engaged follicular B cells initially reduce their migration velocity upon antigen exposure. About 6 hours later, the activated B cells move toward the follicle border with the T-cell-rich zone and undergo highly dynamic interactions with helper T cells during the following several days.[310]

In the spleen, a subpopulation of B cells is lodged in the marginal zone (MZ) immediately adjacent to the marginal sinus that surrounds the white pulp cords. The exact extent to which chemokine-induced attraction and adhesion affect the positioning of MZ B cells is still unclear. However, recent studies indicate that the lodgment of B cells in the MZ is dependent upon interactions of αLβ2 and α4β1 on MZ B cells with their ligands (ICAM-1 and VCAM-1, respectively).[341,342] As with follicular B cells in LN, antigen encounter of MZ B cells causes their rapid repositioning to the B-T boundary area. The retention of naive B cells in the MZ and their relocalization to the B-T boundary area upon antigen encounter is thought to involve signaling through the phospholipid sphingosine-1 phosphate (S1P) and its receptor $S1P_1$.[343]

LEUKOCYTE EXIT FROM TISSUES

While the coordinated role of adhesion molecules and chemokines governing lymphocyte entry into tissues has been examined in great detail, less is known about the exit of these cells from tissues. The final sections of this chapter will discuss examples of emerging research on the diverse mechanisms that regulate exit of distinct leukocyte subsets from tissues.

Reprogramming Dendritic Cells to Exit Tissues Toward Secondary Lymphoid Organs

Lymphocyte homing remains without consequence unless lymphocytes encounter dendritic cells that present their cognate antigen. Dendritic cells capture and present antigens to T cells more efficiently than any other antigen-presenting cell. In general, two routes of antigen delivery to LNs have been described to date. (1) Antigenic material becomes lymph borne and is taken up by dendritic cells that reside in the LN a priori; (2) Antigen is acquired by dendritic cells that reside in peripheral tissues and then transport the material to the draining LN. Dendritic cells constitutively patrol all tissues and engulf microorganisms, dead cells, and cellular debris. In the absence of inflammatory stimuli, the cells remain in an immature state that is only weakly immunogenic and often stimulates T-cell tolerance, rather than activation. However, multiple signals associated with infection or tissue damage can induce dendritic cell maturation. Immature dendritic cells express many chemokine receptors, including as CCR1, CCR5, and CCR6, which are believed to result in the constitutive homing of immature dendritic cells into tissues, particularly sites of inflammation where ligands for these receptors are abundant.[4,201,344–346] After exposure to a maturation stimulus, such as Toll-like receptor agonists (e.g., LPS, bacterial lipoproteins, peptidoglycans or CpG dinucleotides), which often originate from infectious pathogens,[347,348] dendritic cells lose CCR1, CCR5, and CCR6, while expression of GPCRs for lymphoid chemokines, in particular CCR7 and CXCR4 are upregulated.[349] Lymphatic endothelial cells in peripheral tissues express CCL21, the ligand for CCR7.[350] The loss of chemokine receptors that keep the dendritic cells within the tissue together with the increased expression of CCR7 results in the exit of the mature dendritic cells via the lymphatic drainage system.[225,351] Recently, using a microfluidic device that allows rapid establishment of stable gradients in three-dimensional matrices, it was shown that CCL21 is a more potent directional cue for DC migration than CCL19.[352] DC migration into the draining lymphatics requires also β2 integrin binding to ICAM-1 expressed by lymphatic endothelial cells. Moreover, junctional adhesion molecule A (JAM-A), which is expressed by DCs and the lymphatic endothelium—also affects DC migration to LNs, because the absence of JAM-A expression by DCs facilitates their migration to LNs.[203,353] The expression and activation of β1-integrins, which mediate the interaction of DCs with extracellular-matrix components, might favor retention of DCs in the periphery.[203]

While traveling to the draining LN, dendritic cells upregulate the expression of molecules for efficient antigen presentation and T-cell stimulation, and begin to generate chemokines and other cytokines, that allow them to attract and stimulate T cells.[351,354,355]

Egress of Lymphocytes From Secondary Lymphoid Organs

When naive lymphocytes do not encounter antigen on antigen-presenting dendritic cells after a period of random walk, they exit SLO through efferent lymph vessels or, in case of the spleen, by directly returning to the blood. Several adhesion receptors have been implicated in the egress of lymphocytes into lymphoid sinusoids, including PECAM-1 (CD31), the mannose receptor, which interacts with

L-selectin, and common lymphatic endothelial and vascular endothelial receptor 1 (CLEVER-1).[356]

We still have very limited information about the signals that determine the dwell time of lymphocytes in SLO (about 12 to 24 hours for T cells). However, the recent observation that the egress of both T and B cells from LN can be prevented by the immunosuppressant molecule FTY720, has revealed some of the principal mechanisms underlying lymphocyte egress. FTY720 is a synthetic derivative of myriocin, a metabolite of the fungus Isaria sinclairii, which has been used in Chinese traditional medicine. FTY720 induces lymphocyte sequestration in LN and causes profound lymphopenia. In animal models of transplantation and autoimmunity, FTY720 causes immunosuppression and it has recently been shown to exert significant therapeutic effects in a placebo-controlled clinical trial of relapsing multiple sclerosis.[357–359] While lymphocyte sequestration in LN and lymphopenia in response to FTY720 have been reported some time ago, the underlying molecular mechanisms were uncovered only recently.[199] Upon in vivo administration, FTY720 becomes rapidly phosphorylated and then binds to four of the five known S1P receptors (S1P$_1$and S1P$_{3–5}$).[194,360–362] Naive B and T cells express substantial levels of S1P$_1$, and it appears to be this receptor that plays a predominant role in lymphocytes egress from lymphoid tissues into the efferent lymph vessels. Studies using gene-targeted mice have shown that T lymphocytes deficient in S1P$_1$ cannot exit SLO (and in case of T cells also the thymus).[363,364] Reports using FTY720 and S1P$_1$-selective agonists also supported a role for S1P-S1P$_1$ signaling in the regulation of lymphocyte egress from SLOs. Notably, S1P$_1$ receptors not only regulate lymphocyte exit from tissues, but also modulate lymphocyte homing capacity.[206]

The sphingolipid S1P is abundant in blood and lymph while low levels of S1P are maintained within lymphoid tissues. This S1P gradient is established by the action of the S1P degrading enzyme S1P lyase.[365–367] Based on these findings, it has been proposed that S1P gradients between blood, lymphoid tissue, and lymph fluid together with cyclical ligand-induced modulation of S1P1 on recirculating lymphocytes regulates lymphocyte egress and determines the lymphoid organ transit time of lymphocytes.[256,368] Indeed, recent observations support that concept by showing that S1P1 on lymphocytes is downregulated in the blood, upregulated in lymphoid organs, and downregulated again in the lymph.[366] Notably, CD69, which is rapidly induced when T cells become activated negatively regulates S1P1 and thus promotes lymphocyte retention in lymphoid organs.[369,370]

Besides chemokines, other factors are also involved in the migration patterns of lymphocytes. By combining confocal, electron, and intravital microscopy, it has been found that the FRC network regulates naive T-cell access to the paracortex, whereas a distinct FDC network served as the substratum for movement of follicular B cells.[324] These results highlight the central role of stromal microanatomy in orchestrating cell migration within the LN.

Although the mechanism of HSPCs homing into the BM are well investigated, little is known about the signals regulating the exit of HSPCs out of tissues other than the BM. HSPCs arrive in peripheral organs via blood, but leave them predominantly via the draining lymphatics.[256,371] Interestingly, it has been shown that, like on the lymphocytes, S1P and S1P receptors mediate the egress of HSPCs from peripheral tissues.[6,7,256] The inhibition of S1P–S1P receptor signaling decreases the number of HSPCs in tissue-draining lymph due to impaired egress from the tissue. Stress signals that mimic an infection (induced by administration of a TLR4 agonist) reduce S1P1 expression on HSPCs, leading to the prolonged retention in peripheral organs, thus providing necessary time for HSPCs to differentiate into immune cells that are required to eliminate the danger. HSPC retention tuning in peripheral tissues could support innate immune responses by fostering a local and versatile supply of effector cells.

SUMMARY

In this chapter, we have outlined three distinct aspects of leukocyte trafficking: (1) **leukocyte entry into tissues** from the circulation; (2) **migration within tissues**; and (3) **exit from tissues**. Migration of leukocytes throughout the body is essential for the development of lymphocyte subsets and underpins their functions in immune surveillance and responses of effective adaptive immunity. The molecular reactions involved in leukocyte migration are tightly regulated and involve chemoattractants and adhesion molecules. Leukocyte migration is characterized by a considerable plasticity and specificity, since different leukocyte subsets express unique patterns of traffic molecules that enable their navigation into and within target tissues. Our expanding knowledge of the mechanisms that control leukocyte trafficking will likely influence the development of multiple therapeutic strategies, including the use of stem cells, cell immunotherapy of cancer, autoimmune, inflammatory, and infectious diseases.

CHAPTER 13

STEM CELL MODEL OF HEMATOLOGIC DISEASES

Omar Abdel-Wahab

CELL-OF-ORIGIN STUDIES IN HEMATOLOGIC MALIGNANCIES

One of the prevailing models of cancer development proposes that a cancer is initiated and maintained through the function of CSCs, which represent a rare population of cells within a cancer that have an indefinite proliferative potential and are ultimately responsible for the generation of the bulk of cancer cells. This so-called CSC hypothesis has been best studied in hematopoietic malignancies. The ability to purify hematopoietic cells more easily than cells from other tissues, combined with the well-defined cell-surface markers of hematopoietic cells, has allowed the prospective isolation of nearly every hematopoietic cell subset from humans as well as mice.

The CSC hypothesis proposes that cancers are organized into hierarchical populations like normal tissues. At the apex of hierarchy are largely quiescent long-lived CSCs with marked self-renewal capacity that sustain the disease and give rise to the majority of the bulk cancer cells that constitute the disease. While identification of a single normal hematopoietic cell subset as the target of the malignant transformation and the cellular reservoir for disease has been possible for a variety of myeloid leukemias and lymphomas, pinpointing a single cell as the target of malignant transformation has not yet proven possible for other hematopoietic malignancies. In this chapter, we discuss efforts to identify the malignant stem cell for each of the common forms of myeloid and lymphoid leukemias.

ACUTE MYELOID LEUKEMIA

The first evidence of a stem cell origin of malignancy came from studies in 1997 performed by Blair et al.,[1] as well as Bonnet and Dick[2] in acute myeloid leukemia (AML). These studies demonstrated that most leukemia cells were unable to proliferate extensively and that only a subset of cells was consistently clonogenic. In these studies, a small subset of human Thy1$^-$CD34$^+$CD38$^-$ AML cells (0.2% to 1.0%) was identified and shown to be the only cells capable of transferring human AML to immunodeficient mice. In humans, normal hematopoietic stem cells (HSCs) reside in the lineage-negative (Lin$^-$) CD34$^+$CD38$^-$CD90$^+$CD45RA$^-$ compartment and generate multipotent progenitors with lymphomyeloid potential (LMPPs) defined as Lin$^-$CD34$^+$CD38$^-$CD90$^-$CD45RA$^-$ cells, as well as more committed myeloid progenitors that are present in the CD34$^+$CD38$^+$ compartment (see Chapter 9).[3] Among the myeloid progenitors, the common myeloid progenitors (CMPs), granulocyte-macrophage progenitors (GMPs), and megakaryocyte-erythroid progenitors (MEPs) can be discriminated based on the differential expressions of CD123 (IL3RA), CD110 (MPL), and CD45RA.

The initial observation that AML leukemia-initiating cells (LICs) reside within the CD34$^+$CD38$^-$ compartment suggested that AML HSCs are rare cells that most closely resemble normal HSCs, sharing a common limited immunophenotype and being a rare population (Fig. 13.1). However, subsequent data have suggested that this conclusion is an oversimplification and that the cell of origin of any myeloid malignancy is likely dictated by a combination of the specific genetic and epigenetic alterations present in the individual patient as well as the cells in which these alterations occur.[4,5] For example, the aforementioned earliest studies of LICs in AML relied on their transplantation into immunodeficient nonobese diabetic/severe combined immunodeficient (NOD/SCID) mice (see box on Evolution of Immunodeficient Mouse Models) to assay the ability of a defined population of AML cells to give rise to AML in vivo. However, using more immunodeficient xenotransplant models, primary human cells from both CD34$^+$CD38$^-$ and CD34$^+$CD38$^+$ compartments have been shown to have LIC activity. In addition, work by Vyas and colleagues has revealed that two expanded populations, both with LIC activity, exist in CD34$^+$ AML (see Fig. 13.1).[9] One population shares the immunophenotype of normal LMPPs and the other mirrors the GMP population. The LMPP-like leukemic stem cell (LSC) population can give rise to the GMP-like LSC population, but either can give rise to AML in immunocompromised mice in vivo.

As described in the box on Functional Evaluation of Cell-of-Origin In Vivo, the leukemogenic effects of specific oncogenes directly depend on the specific oncogene as well as the target cell of expression. Based on these facts, consistent LICs may be most easily defined for specific genetically defined subsets of leukemias (such as specific chronic leukemias defined by specific translocations or point mutations) but are much more difficult to define for normal karyotype AML. For example, expression of the *AML1-ETO* fusion transcript, generated by the common t(8;21) translocation in AML, can

EVOLUTION OF IMMUNODEFICIENT MOUSE MODELS

Xenotransplantation of human hematopoietic cells into immunocompromised mice has been an important assay for studying normal and malignant human hematopoiesis for more than 50 years.[6] The first breakthrough in xenograft modeling of human hematopoiesis was the discovery of the severe combined immune-deficient (SCID) mouse. Transplantation of human bone marrow cells into the SCID mouse not only regenerated T and B cells, which the mice lacked genetically, but also continued to generate myeloid progenitors long term. SCID mice are limited by high levels of innate immune function that impede human engraftment, however. To circumvent this limitation, SCID mice were back-crossed onto nonobese diabetic (NOD) mice harboring innate immune defects. NOD-SCID mice support higher levels of human engraftment but are limited by the development of thymic lymphomas and the persistence of functioning natural killer (NK) cells. Both of these problems were addressed by deletion of the IL-2 receptor common gamma chain. Resultant NOD/SCID/gamma-null (NSG) mice have complete loss of B, T, and NK cells; and their defective cytokine signaling also prevents lymphomagenesis. NSG mice support higher levels of human donor cell engraftment and serve as assays that functionally assess the ability of potential cancer stem cells to initiate a malignancy. Newer types of humanized mice, such as the MISTRG mouse, have been developed that express human cytokines that are not cross-reactive with murine cells and are able to stimulate the growth of more human cell types in vivo.[7] Other humanization strategies include constitutive expression of HLA class I and II that strengthens T-cell function or constitutive expression of Sirpa, a transmembrane protein on macrophages that induces tolerance to human grafts. Loss-of-function mutations in KIT proto-oncogene receptor tyrosine kinase (KIT) has allowed for the creation of hematopoietic stem cell (HSC) xenografts without the need for irradiation of the recipient mouse.[8]

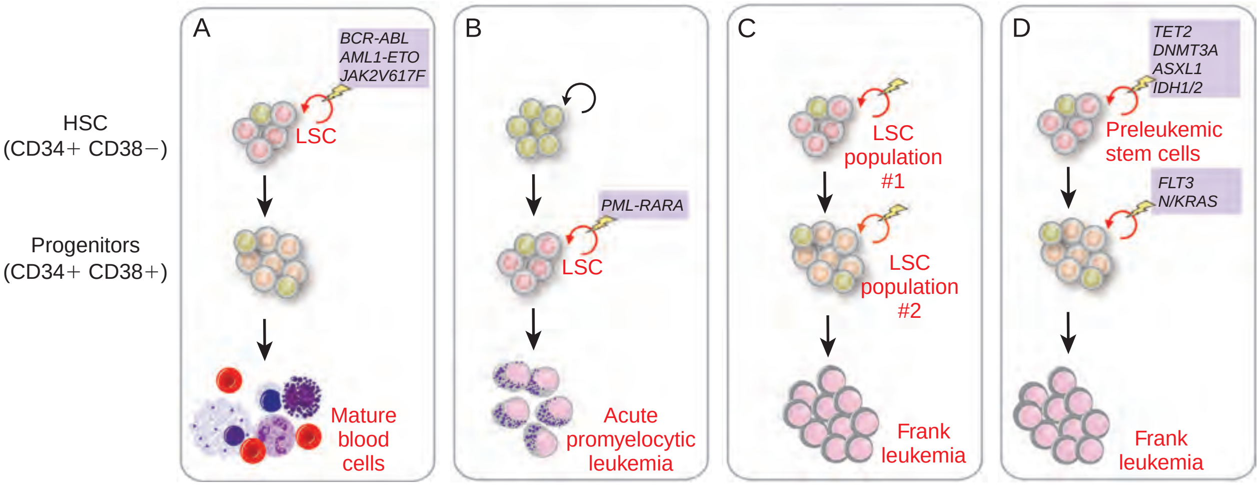

Figure 13.1 SCHEMATIC MODELS DEPICTING THE ORIGIN OF LEUKEMIC STEM CELLS (LSCS) IN VARIOUS MYELOID MALIGNANCIES. (A) Genetic evidence from some forms of acute and chronic myeloid leukemias reveals that the inciting genetic event occurs in a cell type in which normal hematopoietic stem cells (HSCs) are enriched (lineage-negative (Lin$^-$)CD34$^+$CD38$^-$). For example, the *AML1-ETO* and *BCR-ABL* translocations found in acute myeloid leukemia (AML) and chronic myeloid leukemia (CML) are present in HSCs. In addition, the *JAK2*V617F mutation is present in HSCs. However, the presence of these mutations alone may not be sufficient to generate overt AML and may be associated with aberrant self-renewal (as is the case with *AML1-ETO*) or chronic myeloproliferation (as with *BCR-ABL* and *JAK2*V617F) alone. (B) In contrast, other forms of AML appear to be generated due to the acquisition of genetic alterations in a cell type more differentiated than HSCs. For example, *PML-RARA* translocations occur in Lin$^-$CD34$^+$CD38$^+$ cells in patients with acute promyelocytic leukemia (APL). (C) In addition, in a proportion of patients with de novo non-APL AML, LSC activity may be present in a cell with an immunophenotype distinct from HSCs. In some cases, multiple populations of LSCs may be present, each with a distinct immunophenotype as shown. (D) Finally, most recently, it has been proposed that genetic alterations may occur in a proportion of HSCs in patients with AML and that confer aberrant self-renewal properties to these cells. Further stepwise accumulation of genetic alterations then occurs in these preleukemic HSCs results in an overt malignant phenotype. As shown, mutations associated with the preleukemic HSCs include genes affecting DNA methylation and chromatin state, whereas mutations associated with frank leukemia include genetic alterations associated with increased cell proliferation.

be detected not only in leukemic cells but also in normal HSCs from patients in clinical remission from AML.[11] However, these *AML1-ETO*-expressing HSCs are not leukemic and can differentiate into myeloid and erythroid cells in vitro in a manner similar to HSCs without the *AML1-ETO* fusion transcripts (see Fig. 13.1). Similarly, analysis of mice expressing the *AML1-ETO* fusion from the endogenous *Aml1* locus in vivo has revealed that *AML1-ETO*-expressing HSCs have aberrant self-renewal capacity but do not develop overt leukemia unless additional genetic abnormalities are present. These data strongly suggest that the acquisition of additional genetic abnormalities in a subset of HSCs or their progeny is required to give rise to overt leukemia. In these studies, the HSCs bearing the *AML1-ETO* fusion reside within the Lin$^-$CD34$^+$CD38$^-$ subpopulation that is also the immunophenotype of normal human HSCs, suggesting that the initiating lesion must occur in a cell with an immunophenotype of normal HSCs. However, leukemic cells from 30% to 40% of patients with AML do not express CD34, and LICs from some patients with AML can actually be CD34$^-$. Interestingly, prior work evaluating the location of the *PML-RARA* transcript present in acute promyelocytic leukemia (APL) revealed that the PML-RARA translocation is actually present in CD34$^-$CD38$^+$ populations and not in CD34$^+$CD38$^-$ HSC-enriched populations (see Fig. 13.1).[12] These data clearly reveal that there is enormous heterogeneity in the cell-of-origin of AML.

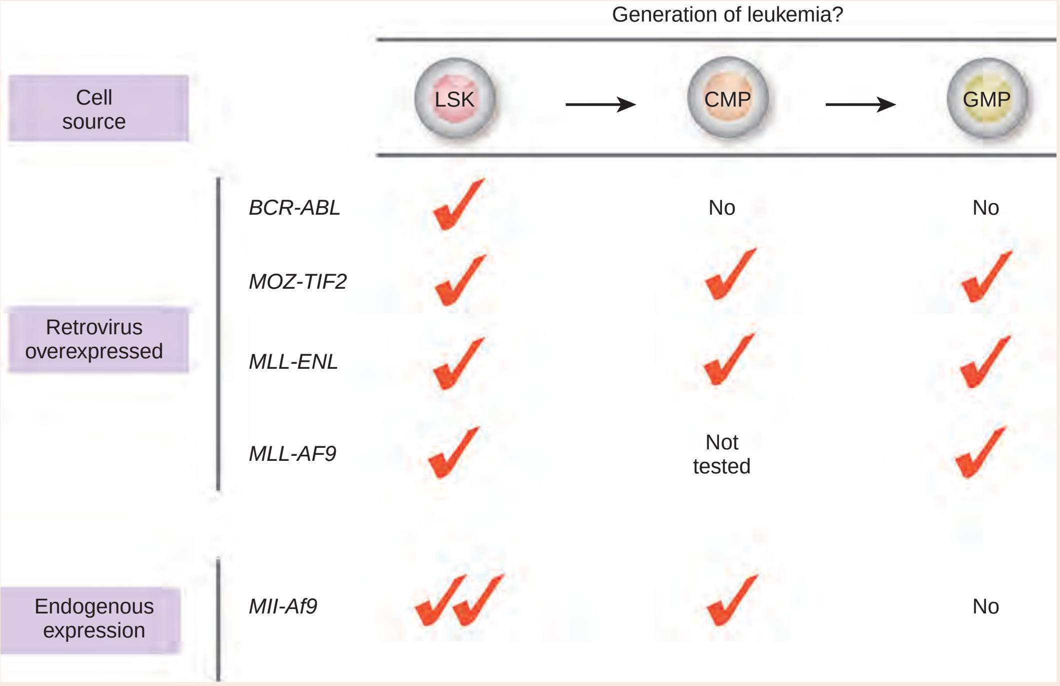
Advancement in techniques to map genetic alterations in cancer has allowed for much finer tracking of somatic mutations in AML and other hematopoietic malignancies with a normal karyotype. It is now believed that an average of five coding mutations is present in adults with de novo AML (see Chapter 59). Several groups have now studied the occurrence of somatic mutations in bulk AML cells and the remaining seemingly nonaffected HSCs. This work has clearly shown that the HSC compartment in patients with AML contains HSCs with none of the mutations found in the AML as well as HSCs with various combinations of genetic alterations similar to that present in the bulk malignant cells (see Fig. 13.1). These latter HSCs are now understood to be “preleukemic stem cells” that initiate AML and can also be identified in remission samples, indicating that they are able to survive induction chemotherapy (see box on Preleukemic Stem Cells).[19–21] Many of the mutations that occur in preleukemic HSCs confer growth properties that allow them to outcompete normal HSCs and presumably lead to relapse. Interestingly, mutations occurring in preleukemic HSCs are enriched in genes regulating DNA methylation, chromatin modifications, and the cohesin complex, while genetic alterations activating signaling are often present in more downstream overt malignant cells and absent from preleukemic HSCs. A series of recent studies performing single-cell mutational analysis of AML have further solidified these findings and identified that mutations in signaling genes (such as FLT3, NRAS, and KRAS) are often acquired in subclones of AML and can be acquired in multiple distinct subclones.[22–25]

MYELODYSPLASTIC SYNDROMES

Similar to AML, tracking major chromosomal abnormalities allowed earlier investigators to establish that clonal hematopoiesis in MDS originated in HSCs (see Chapter 61). Initially, deletion of the long arm of chromosome 5 (del(5q)) was identified in the HSCs of patients with del(5q)-MDS. Moreover, del(5q) CD34$^+$CD38$^-$ cells were shown to possess MDS-initiating potential using in vitro and in vivo stem cell assays. Systems subsequently improved phenotypic identification of HSCs that have allowed investigators to focus on Lin$^-$CD34$^+$CD38$^-$CD90$^+$CD45RA$^-$ cells as candidate CSCs in MDS. These studies showed that in patients with del(5q)-MDS, 99% of Lin$^-$CD34$^+$CD38$^-$CD90$^+$CD45RA$^-$ cells contained del(5q) and that they were molecularly and functionally distinct from clonally involved GMPs and MEPs.[26] By gene expression profiling and

FUNCTIONAL EVALUATION OF CELL-OF-ORIGIN IN VIVO

The earliest studies of cancer stem cells in acute myeloid leukemia (AML) suggested that AML is initiated by genetic alterations that take place in hematopoietic stem cells (HSCs). Alternatively, however, there is clear evidence that some leukemias may be initiated by mutations arising in more committed progenitors that provide these cells with aberrant self-renewal capacity that they otherwise lack. Numerous studies have attempted to directly address each of these possibilities through selective expression of specific oncogenes in isolated HSCs, common myeloid progenitors (CMPs), granulocyte-macrophage progenitors (GMPs), and even more mature myeloid cells (Fig. 13.2). Such experiments have been most thoroughly performed using the expression of mixed lineage leukemia (MLL) fusion oncoproteins. *MLL* encodes an epigenetic enzyme required for normal hematopoiesis due to its role in the maintenance of *HOX* gene expression (see Chapter 9). Translocation events fusing the N-terminus of MLL to over 50 different C-terminal partners are common in both AML and acute lymphoblastic leukemia (ALL). Overexpression of the *MLL-ENL* fusion oncoprotein in self-renewing HSCs as well as in myeloid progenitor populations with more restricted self-renewal potential including CMPs and GMPs result in the rapid onset of AML in vivo.[10] Similar results have been seen with retroviral overexpression of a different MLL fusion oncoprotein, *MLL-AF9*, as well as an unrelated AML-associated fusion, *MOZ-TIF2* (see Fig. 13.2). In contrast, overexpression of *BCR-ABL* is only able to transform HSCs but not committed downstream progenitors. These results unequivocally demonstrate (1) the ability of an MLL fusion oncoprotein to convert a myeloid progenitor cell population that is distinct from an HSC to acquire leukemogenic self-renewal activity and (2) that the cell-of-origin where a genetic alteration is expressed may regulate the resultant ability for a malignant disease to develop. It is also important to note that when the MLL-AF9 fusion is expressed under endogenous regulatory control, *Mll-Af9* transforms HSCs but not GMPs. These data clearly reveal that the dosage of oncogene expression may also regulate cellular transformation.



Cell source		Generation of leukemia? LSK	CMP	GMP
Retrovirus overexpressed	*BCR-ABL*	✓	No	No
	MOZ-TIF2	✓	✓	✓
	MLL-ENL	✓	✓	✓
	MLL-AF9	✓	Not tested	✓
Endogenous expression	*Mll-Af9*	✓✓	✓	No

Figure 13.2 LEUKEMIC CELL-OF-ORIGIN DEPENDS ON THE GENETIC ALTERATION, THE CELLULAR CONTEXT, AND GENE DOSAGE. Schematic of experiments testing the leukemogenic effects of retroviral overexpression of a number of leukemogenic fusions in hematopoietic stem and progenitor cell populations from mice followed by their transplantation into recipient mice. Mouse cell populations studied include the hematopoietic stem cell enriched LSK cell population as well as the common myeloid progenitor (CMP) and granulocyte-macrophage cell progenitor population. While retroviral overexpression of MLL-AF9 transforms LSK cells, CMP, and granulocyte-macrophage progenitor (GMP) populations, expression of MLL-AF9 from its endogenous locus efficiently transforms LSK cells but is only able to transform a proportion of CMP cells and is unable to transform GMPs.

principle component analysis of RNA sequencing data, the three cell populations were shown to be distinctively different, with the Lin$^-$CD34$^+$CD38$^-$CD90$^+$CD45RA$^-$ cells selectively expressing genes characteristic of normal HSCs. These candidate stem cells were exclusively able to sustain long-term generation of MDS myeloid progenitors in vitro that was not observed with GMPs, MEPs, or CMPs. Moreover, patients with del(5q)-MDS were found to have residual del(5q) clones in the CD34$^+$CD38$^-$CD90$^+$ stem cell compartment during clinical remission.[27] Over time, most of these patients experienced expansion of the clone, leading to cytogenetic and clinical progression.

The evidence for an MDS-initiating stem cell is not limited to isolated del(5q)-MDS, which may be a unique disease entity given its distinct clinical features. In fact, recent studies have shown that recurrent driver mutations occur at the HSC level in a broad panel of low to intermediate risk MDS and that the 5q deletion preceded any other identifiable recurrent driver mutations in isolated del(5q)-MDS. The same was observed with *SF3B1* mutation-positive MDS that is characterized by ringed sideroblasts, where *SF3B1* mutations are thought to be early and potentially initiating events. Targeted screening for mutations of a large number of genes known to be frequently mutated in MDS and other myeloid malignancies has been performed on bulk bone marrow from patients with MDS. After identifying the mutations specific to each patient, the different cell compartments (HSC, GMP, or MEP) were purified and the screen for mutations was repeated. It was hypothesized that if progenitor cells acquired self-renewal

PRELEUKEMIC STEM CELLS

Hematopoietic stem cells (HSCs) are rare (~1–2 per 10^8 bone marrow cells) and quiescent cells that rarely divide. However, all blood cells originate from progenitor cells that in turn originate from HSCs and thus HSCs must replicate/self-renew to continue the cycle. Mutations in HSCs can therefore occur during cell division and accumulate, sometimes speeding self-renewal divisions and leading to clonal hematopoiesis. Although able to confer a growth advantage to clones derived from mutated HSCs, these single mutations alone are not sufficient to transform cells, resulting in an overt malignant phenotype. Because growth-promoting gene mutations are common in cancer, it is thought that HSCs with mutations that cause clonal hematopoiesis might exist as preleukemic stem cells in patients with leukemia for months to years prior to diagnosis (see Chapter 59). Cooperative driver mutations are then acquired that cause cancer to develop. Acquired somatic mutations causing clonal hematopoiesis exist in healthy individuals and increase in frequency with age.[13–15] The risk of hematologic malignancy is higher in patients with clonal hematopoiesis compared with matched controls, providing evidence for leukemic predisposition (see Chapter 59). The most common mutations causing clonal hematopoiesis were found in the genes for *DNMT3A*, *TET2*, *SRSF2*, *SF3B1*, *U2AF1*, *IDH1/2*, and *ASXL1* which are also known to be recurrently mutated in myeloid malignancies. These genes encode proteins involved in epigenetic modifications of chromatin and DNA as well as in RNA splicing.[16] Functional experiments have shown that DNMT3A and TET2 actually increase the number of HSCs in the bone marrow due to impaired differentiation and increased self-renewal, respectively. Studies of a few patients with preleukemic stem cells who went on to develop leukemia have shown that at least in some cases, the leukemia developed only after acquisition of another driver mutation such as mutations in *FLT3*.[14] Additionally, different somatic mutations drive distinct patterns of clonal hematopoiesis, such as mutations in the splicing factors U2AF1, SF3B1, and SRSF2, which exclusively occur in patients over the age of 70 and may only confer a growth advantage under the selection pressures of an aging hematopoietic system.[17,18]

capacity, allowing them to persist long enough for the mutations to be responsible for the MDS phenotype, then the mutations would be identifiable in progenitors but not within HSCs. However, all of the mutations in MDS patients have been traced back to the HSC compartment ($Lin^-CD34^+CD38^-CD90^+CD45RA^-$ cells) and all of the mutations found in the $Lin^-CD34^+CD38^-CD90^+CD45RA^-$ MDS-initiating cells have also been identified in downstream GMPs and MEPs.[26] These findings suggest that MDS is propagated by a stem cell that develops and acquires mutations at an early stage in the disease.

Interestingly, Chen and colleagues provided evidence for a nonlinear, parallel manner by which MDS patient HSCs progress to AML.[28] They identified distinct progenitor populations that gave rise to MDS and MDS-related AML. They demonstrated that the dominant AML clone originated from a clone that was included in as pre MDS and/ or MDS HSCs but was undetectable in the MDS blast cells, indicating MDs stem cells are distinct from those that contribute to AML that follow MDS.

MYELOPROLIFERATIVE NEOPLASMS

The translocation between chromosomes 9 and 22, the so-called Philadelphia chromosome, is the hallmark of chronic myeloid leukemia (CML) (see Chapter 69) and gives rise to the *BCR-ABL* oncogene and its constitutively active protein tyrosine kinase product $p210^{BCR\text{-}ABL}$. In patients with CML, there is a clonal expansion of HSCs, and the BCR-ABL translocation can be detected in HSCs from patients with CML as well as all myeloid as well as even committed lymphoid cells generated by these HSCs (see Fig. 13.1). The data clearly identify chronic phase CML as a stem cell disorder in which the target cell of transformation is an HSC. This is a finding that has direct therapeutic implications as ABL kinase inhibitors, which are used clinically for CML, do not consistently eradicate the quiescent *BCR-ABL*–positive CML LICs.

In contrast to the chronic phase of CML where the normal HSC appears to be the target cell-of-origin, transformation of CML in the myeloid blast crisis appears to be associated with the expansion of a more committed myeloid progenitor population (which consists mostly of GMPs) rather than expansion of the HSC population. The GMPs from blast crisis patients with CML actually have the ability to serially replate in vitro, a proxy of aberrant self-renewal capacity not seen in normal GMPs. These data suggest that disease progression from chronic phase to myeloid blast crisis occurs due to aberrant acquisition of self-renewal potential within the committed GMP population, a possibility that has been directly studied in animal models (see Fig. 13.2 and box on Functional Evaluation of Cell-of-Origin In Vivo.)

The other chronic myeloproliferative neoplasm besides CML in which a specific genetic alteration is present in nearly 100% of patients is polycythemia vera (PV); a single mutation results in the substitution of phenylalanine for valine at codon 617 of the Janus kinase 2 (JAK2) tyrosine kinase in nearly every patient (see Chapter 70). Targeted sequencing of *JAK2* in patients with PV showed that the *JAK2*V617F mutation is present in cells with an HSC phenotype (see Fig. 13.1).[29] Moreover, HSCs from patients with PV are skewed toward the erythroid lineage at the HSC level already and there is also an expansion of the CMP pool, suggesting that expression of the *JAK2*V617F mutation affects HSC and progenitor cell populations. Interestingly, early efforts to study the effects of JAK inhibition in PV revealed that JAK inhibition exhibited inhibitory effects on the erythroid potential of PV HSCs but did not result in preferential eradication of *JAK2*V617F-mutant HSCs versus normal HSCs. Thus, this finding of an HSC origin for PV has direct therapeutic implications, as curative eradication of the disease would require therapy that eliminates rare quiescent bone marrow–based HSCs.

ACUTE LYMPHOBLASTIC LEUKEMIA

Unlike the myeloid malignancies, it has been less clear whether lymphoid malignancies also arise from an HSC or have a different cell-of-origin. In B-cell acute lymphoblastic leukemia (B-ALL) (see Chapter 66), considerable effort has gone into answering this question (Fig. 13.3). Early studies in specific subtypes of B-ALL supported a preleukemic stem cell such as identified in AML. *TEL/AML-1* rearranged ALL has been particularly well studied and is associated with a good prognosis. These studies showed that *TEL/AML-1* alone is insufficient for leukemogenesis. In fact, the frequency of *TEL/AML-1* in healthy infants far exceeds the incidence of ALL, suggesting that the development of leukemia requires a second hit. This is evident from studies of pairs of twins, both with evidence of a preleukemic *TEL/AML-1* $CD34^+CD38^-CD19^+$ population of cells, where one twin developed ALL and the other did not. The healthy twin retained the preleukemic population, which showed evidence of self-renewal and hierarchical differentiation. Later studies of high-risk ALL showed that leukemogenic potential may also be present in more differentiated cell populations, such as $CD34^-CD19^+$ cells (see Fig. 13.3). Recent extension of this work to B-ALL cases with a variety of chromosomal abnormalities has found that even mature blasts expressing CD20 were able to establish leukemia upon transplantation into immunodeficient mice. Also, as many as 1 in 40 B-ALL blasts retained leukemogenic potential. Overall, B-ALL blasts do not seem to be hierarchically arranged in a similar fashion as AML, and engraftment of further differentiated $CD34^-$ blasts can give rise to both $CD34^-$ and $CD34^+$ populations in vivo.[30] Together, these data suggest that B-ALL arises in a committed lymphoid progenitor rather than only a small population of cells accumulating mutations and retaining stem cell properties and that most

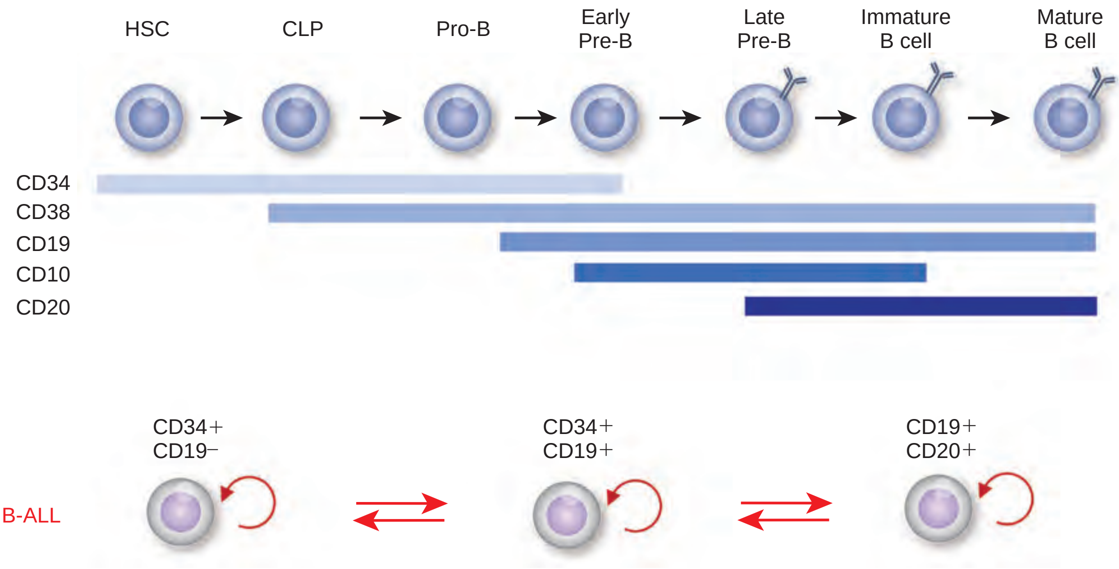


Figure 13.3 STAGES OF NORMAL EARLY B-CELL DIFFERENTIATION AND SCHEMATIC OF LEUKEMIC STEM CELLS IN B-CELL ACUTE LYMPHOBLASTIC LEUKEMIA (B-ALL). Based on several studies testing the ability of human B-ALL blasts to engraft in immune-deficient mice, it appears that multiple blast populations in B-ALL are able to establish the disease in immune-deficient mice. For example, CD34$^+$CD19$^+$ blasts as well as CD34$^-$CD19$^+$ blasts from individual patients have been shown to be able to transplant leukemia in vivo and to give rise to CD34$^+$ and CD34$^-$ leukemic cells. Thus, B-ALL does not appear to follow a hierarchical model in which blasts with a more mature immunophenotype lose their stem cell capacity, as has been seen in some cases of acute myeloid leukemia.

or even all of the leukemic blasts retain the ability to propagate the malignancy.

In contrast to *TEL/AML-1*, those patients with ALL carrying the BCR-ABL fusion protein have much worse clinical outcomes. However, like TEL/AML-1, BCR-ABL is also thought to be a primary mutation that is necessary but not sufficient for ALL transformation. Interestingly, the two BCR-ABL transcripts, P190 and P210, caused by different break points in the t(9;22) translocation, show distinct patterns of HSC and committed B-cell progenitor involvement. In most cases, the P190 BCR-ABL originates in a CD34$^+$CD38$^-$CD19$^+$ progenitor cell while P210 BCR-ABL originates in a multipotent HSC. When purified P210 BCR-ABL HSCs were transplanted into NOD/SCID mice, they exclusively reconstituted normal, BCR-ABL–negative multilineage hematopoiesis.[31] These data suggest that the purified HSC also contain normal HSCs that outcompete the P210 BCR-ABL HSCs, which are not the leukemia stem cells. In contrast, more committed CD19$^+$ P210 BCR-ABL–positive cells resulted in leukemic reconstitution upon transplantation into NOD/SCID mice that was enhanced following secondary transplant. These data complement recent findings suggesting that the primary BCR-ABL translocation in CML originates in HSCs, yet the leukemic transformation in blast crisis results in an LSC with a committed progenitor cell phenotype. This begs the question of whether P210 BCR-ABL–positive ALL represents de novo ALL or CML in lymphoid blast crisis.

MATURE B-CELL MALIGNANCIES

The classification of mature B-cell malignancies based on their histology and immunophenotypic resemblance to a particular stage of lymphoid differentiation has led to the theory that each lymphoma subtype originates within lymphocytes at distinct differentiation stages (Fig. 13.4). Another model predicts that cells acquire initial alterations at early stages, even at the HSC level, that may drive clonal expansion or resistance to apoptosis and that these cells then develop additional complementary alterations at a later stage that lead to overt malignancy. Recent studies have identified novel lymphoid associated mutations and alterations across large panels of lymphomas, creating the opportunity to define the clonal architecture and cell-of-origin in lymphoma subtypes.

CHRONIC LYMPHOCYTIC LEUKEMIA

Chronic lymphocytic leukemia (CLL) is a B-cell malignancy marked by the accumulation of clonal mature B cells in the lymph node, bone marrow, and/or blood. In nearly all cases, CLL is preceded by a preleukemic monoclonal B-cell lymphocytosis (MBL), though not all cases of MBL continue on to CLL (see Chapter 76). The precise cell within B-cell development that gives rise to CLL has been debated for decades, and two studies have implicated HSCs in the pathogenesis of CLL. Kikushige et al. investigated the cellular origin of CLL by isolating distinct subpopulations of cells and assaying their ability to initiate disease in immunodeficient mice. Only the CD34$^+$CD38$^-$CD90$^+$ fraction engrafted and this population, known to be highly enriched in HSCs, gave rise to both lymphoid and myeloid hematopoiesis. Interestingly, these engrafted mice showed an increased proportion of polyclonal B cells and a population of monoclonal B cells expressing CD5, akin to MBL.[32] Further examination determined that they had different variable, joining and diversity segments (V(D)J) rearrangement patterns compared to the prior CLL. The finding of aberrant HSCs in CLL suggests that they are primed to generate MBL cells, which are likely to accumulate additional mutations that eventually result in a clonal CLL disorder.

In a different approach, Damm et al. investigated whether molecular alterations present in CLL cells could be traced to cells in the earliest stages of hematopoietic development before committed B-cell development. In fact, acquired mutations were detected in HSCs in the majority of the patients with CLL studied.[33] These findings support a preleukemic phase and the clinical implications imply that treatments with true curative intent in CLL might require approaches other than those focused solely on cell-surface antigens restricted to B cells or B-cell receptor signaling pathways.

HAIRY CELL LEUKEMIA

Hairy cell leukemia (HCL) (see Chapter 77) is a chronic lymphoproliferative disorder characterized as a mature B-cell malignancy based on the expression of CD19, surface immunoglobulin, and the clonal rearrangement of immunoglobulin heavy and light chain genes. At the same time, HCL cells also express cell-surface markers not present on normal B cells, including CD103 and CD11c, which are typically expressed by dendritic cells and monocytes. In addition, patients with HCL have long been known to have clinical features disparate from most mature B-cell malignancies, including the absence of lymph node involvement and frequent splenomegaly due to extramedullary hematopoiesis (EMH). Recent identification of BRAFV600E mutations in nearly 100% of patients with classic HCL provided genetic insight into the pathogenesis of HCL and a clonal marker to track the origin and propagation of HCL. The BRAFV600E mutation was found in purified (Lin^-) $CD34^+$ CD38 $^-CD90^+CD45RA^-$ HSCs in primary samples from patients with HCL. These aberrant HSCs were also able to recapitulate BRAFV600E-mutant hematopoiesis after transplantation into NOD/SCID/gamma-null (NSG) mice. Additionally, conditional knock-in mice were generated, expressing BRAFV600E in either HSCs or $CD19^+$ cells. Those mice with BRAFV600E HSCs showed an HCL-like phenotype of anemia, thrombocytopenia, and EMH; however, no phenotypic hairy cells were seen. In contrast, mice with BRAFV600E expression limited to lineage-committed B cells did not have reduced survival or an overt phenotype. These data suggest that HCL is initiated within the HSC compartment but that the development of additional genetic alterations occurring along the course of hematopoiesis may be necessary to give rise to HCL cells. Indeed, in patients with genetic alterations in addition to BRAFV600E in HCL cells, these additional mutations were not found in the BRAF-mutated HSCs.[34]

DIFFUSE LARGE B-CELL LYMPHOMA

High-resolution genomic analyses of a large number of human diffuse large B-cell lymphoma (DLBCL) (see Chapters 81 and 85) samples identified copy number gain of chromosome 3q27.2 to be associated with the worst prognosis and the aggressive activated B-cell (ABC) disease subtype. The transcription factor BCL6 is likely the target oncogene affected by this copy number alteration at this locus given its propensity to be targeted by other alterations in DLBCL such as translocations and point mutations, which were mutually exclusive from the 3q27.2 gain. Other roles for BCL6 have been described in normal hematopoiesis and myeloid leukemia stem cells, prompting inquiries into whether BCL6 expression in HSCs has a role in the origins of DLBCL. This hypothesis was tested by the generation of a mouse model that expressed BCL6 only in HSCs under the control of a stem cell-specific promotor so that BCL6 was no longer expressed by the differentiated progeny. These mice developed a form of lymphoma that resembled DLBCL with an ABC phenotype that did not overexpress BCL6.[33] This led to a proposed model of “hit-and-run” oncogenesis, wherein BCL6 expression in hematopoietic precursors is sufficient to produce DLBCL without requiring sustained overexpression.[35]

FOLLICULAR LYMPHOMA

The most common subtype of lymphoma is follicular lymphoma (FL), which is so named because histologically the lymph node follicle B cell is affected (see Chapters 81 and 82). These aberrant B cells carry a hallmark translocation between chromosomes 14 and 18, resulting in the juxtaposition of the immunoglobulin heavy chain gene (IGH) and the antiapoptotic protein BCL-2, thus driving overexpression of BCL2 and resistance to programmed cell death. This malignancy usually follows an indolent course and is more common in elderly patients. It has been shown that up to 25% of healthy individuals harbor BCL-2/IGH rearranged cells yet do not have the disease, indicating that the hallmark lesion is not sufficient to cause lymphoma and that additional genetic mutations must be required for lymphomagenesis. As in other hematologic malignancies, newer sequencing technologies have allowed identification of novel recurrent mutations in FL, and some researchers have begun investigating the timing of those mutations. By taking the opportunity presented by an unfortunate but rare occurrence of donor-derived FL after HSC transplantation, investigators have shown that some of these genetic mutations occur in hematopoietic precursors prior to the cells in which the BCL-2/IGH rearrangement occurs.

HSC donors are screened for signs and symptoms of malignancy but are not currently subjected to genetic testing for premalignant conditions. Often, the donor is a brother or sister due to the 25% chance of being a complete HLA-match and the willingness of a sibling to donate. This inherently means that a sibling donor is at slightly higher risk of having a malignancy given their close relationship to someone with cancer (i.e., the recipient), yet it is still a rare occurrence that donor cells will transfer a malignancy to the recipient after stem cell transplantation. In the case mentioned previously,[36] the donor and the recipient both developed FL 7 years after the transplant. Both patients’ FL had exactly identical BCL-2/IGH rearrangement breakpoints and the same V(D)J recombination, indicating that they were derived from the same mutation. The recipient had received a donor-lymphocyte infusion (DLI) 7 years prior, which also harbored the same BCL-2/IGH and V(D)J rearrangements, thus confirming the donor-derived source. A sample of the original stem cell transplant was not available to test but the BCL-2/IGH rearrangement was not present in the cells other than $CD19^+$ mature B cells in the DLI sample. However, there were mutations known to occur in lymphoma present in the $CD34^+CD10^-CD19^-$ population that includes multipotent progenitors and HSCs.[37] These alterations presumably contributed to the development of FL prior to the acquisition of the hallmark translocation and occur in progenitors of the follicle B cell. These findings provide evidence of a possible role of stem cells in the development of mature B-cell malignancies.

CONCLUSION

The stem cell model of hematologic diseases has implications beyond a theoretical construct for the pathogenesis of disease. Not only does this model support stem cell transplant and gene therapy as curative treatments in some cases, but this model also has much broader application in the management of hematologic malignancies. Most of our current standard therapies are based on the principle of interrupting DNA replication in rapidly dividing cancer cells, yet stem cells are quiescent and spend little time in the active cell cycle. Many of the new and developing therapies are targeted at cell-surface markers or mutated genes whose expression may be restricted to the most mature malignant cells and may be lacking in the premalignant or malignant stem cells. It remains to be seen whether the same challenges will face immune response checkpoint modulators, but one could consider the possibility that neoepitopes recognized by activated T cells might have different expressions on different cell populations.

Remarkable progress has been made in the field of CSCs in hematologic malignancies due to the evolution of immune-deficient mouse models and the improvement of sequencing technologies that have allowed the mapping of clonal evolution and studies of mutational ontogeny. There are controversies from inside and outside of the field as to whether stem cells should be defined phenotypically, molecularly, or functionally; but as the evidence accumulates, there is broad agreement on the stem cell model of hematologic diseases.

Figure 13.4 MODELS OF LYMPHOMA ONTOGENY. (A) The conventional model of lymphoma classifies lymphomas based on the differentiation of mature peripheral B cells. This model is based on the presence of somatic hypermutation as well as immunophenotypic and gene expression analyses comparing the malignant cells to normal B-cell counterparts. (B) At the same time, mature B cells are derived from precursor B cells and earlier progenitor and hematopoietic stem cells (HSCs). In the conventional model *(left)*, it is assumed that cells more primitive than the peripheral B cell depicted in (A) are not involved with the lymphoma disease process. However, there is increasing evidence that HSCs and/or more intermediate progenitors may harbor aberrancies directly linked to mature B-cell malignancies. *ABC DLBCL*, Activated B-cell–like diffuse large B-cell lymphoma; *CLL*, chronic lymphocytic leukemia; *FL*, follicular lymphoma; *GCB*, germinal center B-cell–like DLBCL; *MCL*, mantle cell lymphoma.

CHAPTER 14

HEMATOPOIETIC MICROENVIRONMENT

David Scadden and Lev Silberstein

EVOLUTION OF THE NICHE CONCEPT

In 1868, Ernest Neumann first suggested that blood cells are being replenished throughout postnatal life, and this proposal led to the attempts to localize the place of hematopoiesis. His hypothesis that blood cell production takes place in the bone marrow (BM) was experimentally validated by selective lead shielding of limbs in irradiated animals almost a century later. Notably, these and other studies showed that differentiation pathways of immature blood cells are determined by their location and are different between the spleen and the BM. Based on this difference between BM and spleen, Schofield first proposed that there is a specialized place or niche where stem cells reside and are governed. He succinctly posed in 1978 that "stem cell is seen in association with other cells which determine its behavior."[1]

Trentin further clarified how different sites affected hematopoietic stem/progenitor cell (HSPC) differentiation. Although both spleen and marrow support multiple cell lineages (erythropoietic and granulocytopoietic, for example), the ratios of differentiating cells were distinct—spleen favored erythropoiesis, but BM predominantly supported granulopoiesis. This controlling influence of the surrounding cells was further illustrated by implanting BM stroma into the spleen and showing that hematopoietic cells abruptly changed from erythropoiesis to granulopoiesis at the spleen–BM demarcation. These observations suggest that immature differentiating progenitors require interactions with specific other cell types in a defined *micro*environment.

This chapter reviews the current knowledge of the hematopoietic microenvironment during development and in postnatal life in normal hematopoiesis and in myelodysplasia and leukemia. The opportunities for therapeutic manipulation of the niche in the treatment of these disorders are also discussed. For the related topics on stem cell mobilization, hematopoietic cytokines and the role of microenvironment in lymphoid malignancies, plasma cell disorders, and myeloproliferative conditions, readers are referred to other chapters of this book.

HEMATOPOIETIC MICROENVIRONMENT DURING DEVELOPMENT

In mammals, hematopoiesis during development takes place in distinct extra-embryonic and embryonic sites. Sequentially, it moves from the yolk sac to the aorta-gonad-mesonephros (AGM) region, fetal liver, placenta, and BM (for details, see Chapter 8).

The first definitive adult HSPCs emerge from the floor of the dorsal aorta, more precisely from the AGM region in the midgestation mouse embryo, and the HSPC clusters appear in close association with the aortic endothelium. Phenotypically defined HSPCs (Sca1+ c-kit + CD41+) arise directly from ventral aortic endothelial cells largely triggered by shear and pulsatile pressure forces.[2] Although direct cellular interactions during HSPCs emergence in the embryo remain to be dissected, bone morphogenetic protein 4 (BMP4), fibroblast growth factor (FGF), transforming growth factor (TGF), vascular endothelial growth factor (VEGF)-Flk1, YAP, and piezo signaling pathways are involved.

The placenta has also been identified as a hematopoietic organ during development.[3] Placenta is known to produce hormones that influence vascularization and therefore may affect blood cell production because hematopoiesis and vasculogenesis are tightly coupled. The hematopoiesis-promoting factors may be either produced by the placental trophoblast cells or enter via maternal circulation. Hematopoietic progenitors appear in the placenta at E9, but their number declines by E13. The cells and local factors providing placental hematopoietic support are currently unknown, but mesenchymal/stromal cells have been suggested as candidates. The placental microenvironment is thought to be geared toward supporting the expansion or maturation of HSPCs without their concomitant differentiation.

In the fetal liver, the HSPCs are first detected on day 9 of mouse embryonic development and approximately week 7 in the human. The liver remains the predominant site of blood production until the BM is invested with cells at approximately 11 weeks post conception and becomes the major blood production organ at week 20. Stromal cell lines obtained from the fetal liver are able to support primitive hematopoietic cells in ex vivo cultures. Some of these cells (termed *myelosupportive stroma*) are able to differentiate in vitro into mesenchymal components (osteoblasts, chondrocytes, and adipocytes). The fetal liver niche has been characterized as Nestin expressing periportal cells and hepatic stellate cells expressing stem cell factor (SCF).[4,5]

Despite the differences in the hematopoietic microenvironment between the sites of fetal and adult hematopoiesis, the key components of the molecular milieu are likely to be shared, as evidenced by successful (although limited) engraftment of HSPCs across developmental barriers. For example, AGM- or fetal liver–derived HSPCs are able to engraft in the adult BM. Notably, they have a competitive advantage over their BM-derived counterparts, with the long-term repopulating ability exceeding that of the BM by fivefold. Vice versa, BM HSPCs engraft in the fetal liver when transplanted in utero, although at low efficiency (less than 5% for the whole BM and 0.43% for highly enriched HSPCs), which may be partly attributable to the absence of pre-transplant conditioning.

Multilineage hematopoiesis during development occurs largely by the virtue of sequential HSPC migration from the AGM region to the fetal liver and the BM, as opposed to de novo HSPC generation. Failure of migration to the "next niche," as exemplified by the targeted disruption of the guanine-nucleotide–binding protein stimulatory α-subunit (GS-α), calcium-sensing receptor, or CXCL12/CXCR4 axis (discussed in detail in Chapter 11 on HSPC migration) leads to severe impairment in hematopoiesis. This suggests even in the absence of cell-intrinsic HSPC defects, proper progression of blood cell production throughout developmental critically depends on the ability of the HSPC to sequentially move to the appropriate microenvironmental compartments.

ADULT BONE MARROW MICROENVIRONMENT

Hematopoietic Stem Cell Niches

Location of the Hematopoietic Stem/Progenitor Cell Niche

In mammals, BM is a major site of hematopoiesis throughout life. The niche preserves and dynamically regulates the HSPC pool by providing signals required for maintenance, quiescence, and retention of HSPCs in the BM. However, the location of the HSPC niche within the marrow has been a subject of controversy.[6] The endosteal surface has long been considered the zone in which HSPCs are preferentially located.[7,8] In the setting of irradiation conditioning, this has been directly demonstrated by intravital imaging studies that allow dynamic assessment of the interaction between transplanted HSPC and the niche. Currently, in vivo imaging is limited to calvarial BM, an area in the mouse skull where the bone is very thin, thus permitting penetration of the laser beam into the BM cavity. Using this technique and simultaneous multicolor fluorescent labeling of osteolineage cells (OLCs), HSPCs, and the vasculature, studies showed that in irradiated recipients, transplanted HSPCs home closest to the endosteal surface and individual OLCs, as compared with more differentiated progenitors, and that they are "anchored" to their niches at least through 72 hours.[9] Preferential localization of primitive hematopoietic cells to the endosteal surface under the homeostatic conditions has been also demonstrated, although this analysis was performed using immunostaining of histological BM sections of either femoral bones or the sternum.

However, other studies performed under steady-state (not transplant) conditions indicate that most HSPCs are located in the central marrow in a perivascular position.[10] Vascular integrity is largely lost with transplant conditioning, so it is not surprising that there might be distinctive sites of hematopoiesis under homeostasis. The positioning of cells near vasculature is to some extent inevitable, as the marrow is richly endowed with sinusoidal vessels. Indeed, approximately 40% of the BM is vascular. Nonetheless, selective deletion of factors in primitive mesenchymal cells and endothelial cells provide evidence for them providing a regulatory and therefore, niche role.[11] Positioning of HSPC in BM by detailed 3-D analysis has indicated that the cells distribute equivalently to random dots when quiescent. Only upon activation do they have distinctive localization near CXCL12 cells.[12] Thus, the niche may be more macroarchitectural, with multiple cells contributing to the functional regulation of HSPC.

Functional roles for specific cells have been defined by the deletion of a key niche factor, such as SCF (kit-ligand), from either endothelial or perivascular cells. This was found to lead to decreases in HSPC providing an experimental basis for the notion of a perivascular niche. While the debate about the location of the HSPC niche—and consequently, cell types that serve as niche participants—continues, it is important to bear in mind that HSPCs themselves are molecularly and functionally heterogeneous and that several distinct niches may co-exist to support this heterogeneity, particularly under different conditions such as the stress of transplantation.

Cellular Components of the Hematopoietic Stem/Progenitor Cell Niche

Over recent years, animal studies revealed marked complexity in the cellular and molecular organization of the HSPC BM niche. Furthermore, single-cell analyses of stroma characterizing it by gene or protein expression has provided a complete inventory of the cell types present in the marrow and begun to define changes they undergo with stress.[13–15] Major cellular components of the HSPC niche and the factors that they produce (summarized in Table 14.1) are discussed in the following sections.

Osteolineage Cells

OLCs are a heterogeneous population of mesenchymal cells that line the endosteal surfaces of flat and trabeculated bones at the interface between the bone and the BM and become embedded within the bone matrix upon terminal differentiation. OLCs are thought to originate from mesenchymal stem cells (MSCs) and gradually progress from the early immature progenitors that express OLC-specific transcription factors Runx2 and osterix to mature osteoblasts expressing extracellular matrix protein osteocalcin and eventually to osteocytes.

Several lines of in vivo evidence support a functional role of the OLCs in the regulation of primitive hematopoietic cells. In the studies providing the first experimental evidence for a mammalian niche in vivo, mice with genetically modified OLCs had an increase in the number of activated OLCs and a corresponding increase in the number of HSPCs. This effect was associated with an increased trabecular bone area and an elevated number of trabecular osteoblasts that expressed the Notch ligand Jagged 1. When the OLCs were depleted, there was a reduction in the BM cellularity and migration of hematopoiesis to the extra-medullary sites. Thus, OLCs play a role in the regulation of HSPC pool size. In addition, OLCs participate in controlling HSPC quiescence through contributing to the production of CXCL12, Angiopoietin 1, thrombopoietin, pan-inhibitor of canonical Wnt signaling Dickkopf1 (Dkk1), noncanonical Wnt ligands, and ECM protein osteopontin. Finally, OLCs govern HSPC localization by controlling their egress into blood and return to the BM, a process that forms the basis for clinical peripheral blood stem cell collection for transplantation. When mature OLCs are deleted from bone, there is an increase in the number of circulating progenitors and a decrease in the mobilization of HSPC with G-CSF, indicating that OLC-derived signals retain primitive hematopoietic cells in the marrow. Following G-CSF-induced mobilization, the OLCs in the trabecular bone adapt a flattened morphology with short projections, which is associated with HSPC egress from the niche. Similar changes are seen after treatment with NSAIDs, which are known to enhance G-CSF-induced HSPC mobilization. When CXCL12, a major HSPC chemo-attractant and retention factor, is deleted from the osteoprogenitors using osterix-Cre promoter, increased HSPC mobilization is also observed. Thus, OLCs participate in the BM niche by regulating HSPC number, quiescence, and retention in the BM space.

Despite the evidence presented above, several studies have argued against the role of OLCs in the niche, citing the absence of HSPC changes either in genetic models associated with reduced OLC number or following OLC-specific deletion of HSPC regulators such as kit-ligand or CXCL12. Several experimental factors are likely to account for this discrepancy, including developmental adaptation when the genetic modification is present throughout the ontogeny or inability of genetic tools to target a specific subset within the OLC compartment that serves as a nodal point of the HSPC regulation: several studies suggest that immature OLCs are important for the niche function, while mature OLCs are dispensable. However, these latter cells appear to play a significant role in supporting lymphoid progenitors. They are critical for B-cell maturation, and osteocalcin-expressing cells regulate the production of T-competent progenitors (as shown in the following sections).

Endothelial Cells

Endothelial cells are known to secrete hematopoietic cytokines and express several adhesion molecules such as E-selectin, P-selectin, vascular cell adhesion molecule 1 (VCAM-1), and intercellular adhesion molecule 1 (ICAM-1) that have been shown to participate in cellular interactions within the HSPC niche. The existence of vascular niche for the HSPCs has been supported by in vivo imaging studies showing early homing of transplanted BM progenitors to specific subdomains of the vascular tree as well as by histologic assessment of the BM using CD150 antibody when HSPCs were found to be in close proximity to the BM sinusoids.

Endothelium-derived factors have diverse effects on HSPCs in vivo. For example, E-selectin (which is expressed exclusively in the endothelial cells) negatively regulates HSPC quiescence; consequently, HSPCs from E-selectin KO mice are more quiescent and resistant to irradiation. On the other hand, endothelial-specific deletion of SCF or CXCL12 leads to the respective reduction of the HSPC pool and loss of repopulating capacity. Similar changes are seen upon endothelial-specific deletion of Notch ligand Jagged 1, which in contrast to E-selectin, promotes HSPC quiescence. The heparin-binding growth factor, pleiotrophin, that is produced by sinusoidal endothelial cells also plays a role in the retention and self-renewal of HSPC in BM. It is not established that among endothelial subpopulations it is the arteriolar cells that secrete the predominant regulator of HSPC, SCF.

TABLE 14.1 HSPC Niche Factors and Their Cellular Sources

Factor	Source	Effect and reference
Membrane-bound SCF	Lepr+ perivascular cells, Tie2$^+$ endothelial cells	Maintenance of HSC in the bone marrow[11]
CXCL12	Lepr$^+$ perivascular cells, Tie-2$^+$ endothelial cells	Retention of HSC in the bone marrow (Ding and Morrison, 2013)
	Prx-1$^+$ osteoprogenitors	Retention of HSC, myeloid and lymphoid progenitors in the bone marrow (Ding and Morrison, 2013; Greenbaum et al., 2013)
	Osx$^+$ osteoprogenitors and Col-2.3$^+$ osteoblastic cells	Retention of lymphoid progenitors in the bone marrow (Ding and Morrison, 2013; Greenbaum et al., 2013)
Notch signaling (Jagged1)	VE-cadherin$^+$ endothelial cells, osteoblastic cells (in PPR model)	Maintenance of HSC and regeneration posttransplantation (Poulos et al., 2013) Expansion of HSC and progenitors[7]
Wnt signaling (Canonical)	Col-2.3$^+$ osteoblastic cells (Wnt inhibitor DKK1)	Maintenance of HSC and quiescence (Fleming et al., 2008)
Wnt signaling (Noncanonical)	N-cadherin$^+$ osteoblastic cells	Maintenance of HSC and quiescence (Sugimura, 2012)
E-Selectin	CD-31$^+$ endothelial cells	Promotion of HSC cycling (Winkler et al., 2012)
Pleiotrophin	VEGFR3$^+$/VE-cadherin$^+$ endothelial cells and CXCL12 perivascular cells	Maintenance of HSC and retention in the bone marrow (Himburg et al., 2010, 2012)
Thrombopoietin	Alkaline phosphatase$^+$ osteoblastic cells	Maintenance of HSC and quiescence (Qian et al., 2007; Yoshihara et al., 2007)
Osteopontin	Osteoblastic and other microenvironmental cells	Negative regulation of HSC numbers and maintenance of quiescence (Nilsson et al., 2005; Stier et al., 2005)
TGF-β	Nonmyelinating Schwann cells, megakaryocytes	HSC quiescence (Yamazaki et al., 2011)
Angiopoietin-1	Osteocalcin$^+$ osteoblasts	Promotion of HSC quiescence (Arai et al., 2004)
Robo-4 ligand(s) (Slit2^a)	Bone marrow stromal cells (^{a}Slit2 identified at the mRNA level)	Promotion of HSC homing to the bone marrow (Smith-Berdan et al., 2011, 2012)
Junction adhesion molecule B (JamB)	Osteoblasts, MSCs, endothelial cells	HSC adhesion and quiescence (Archangeli, 2011)
CXCL4	Megakaryocytes	Promotion of HSC quiescence

Perivascular Cells

The observation that HSPCs co-localize with the marrow vasculature raised the possibility that perivascular cells may also play a role in the HSPC regulation by the niche. So far, three types of perivascular cells have been characterized—CXCL 12-abundant reticular cells (CAR cells), nestin-GFP^{dim}/leptinR+ MSCs, and nestin-GFP^{bright}/NG2+ pericytes.[11,16]

CAR cells were identified in a mouse model in which GFP was driven by the CXCL12 promoter. Similar to the other components of the niche, CXCL12-abundant reticular (CAR) cells are found in close proximity to HSPCs. It is likely that they are genetically and phenotypically related to nestin-GFP^{low} cells (see the following section) because their ablation also severely impaired adipogenic and osteogenic differentiation of nonhematopoietic BM cells in addition to reducing the number of HSPCs. Notably, the effect of deletion was not limited to HSPCs but also affected mature lineages, such as lymphoid cells, indicating a wider role for these cells in hematopoietic support.

MSCs are located in the peri-sinusoidal BM space and have been initially defined by low expression of GFP driven by gene regulatory elements of intermediate filament protein Nestin (nestin-GFP^{low}). Nestin-GFP^{low} cells express the genes associated with HSPC retention in the niche (Cxcl12, VCAM-1), which are down-regulated upon GCSF mobilization. Selective deletion of Nestin-positive cells in mice resulted in a 50% reduction in the number of long-term HSPCs and their relocation to the spleen, although it is not clear whether this effect was mediated directly by Nestin-positive cells or through their more differentiated downstream progeny. Subsequent studies revealed that a population that largely overlaps with nestin-GFP^{low} cells can be also defined by the expression of the leptin receptor. Specific deletion of known HSPC regulators (SCF, CXCL12) specifically from MSCs using Cre-recombinase driven by leptin receptor gene regulatory elements lead to a reduction in the HSPC number and long-term repopulating capacity, further delineating the functional significance of MSCs in the HSPC niche.

Leptin receptor-expressing cells (LepR+) are the single largest population of BM stromal cells. While the receptor itself does not appear to be critical, the cells are productive of high levels of SCF and CXCL12 and are shown to be important modifiers of HSPC number. With single-cell analyses, it has become clear that the LepR+ populations are very heterogeneous. It has also been shown that the cells differentiate into both osteoblasts and adipocytes. Since the studies defining the function of these cells have relied upon genetic models where any cell ever expressing LepR deletes the test gene, interpretation should be done with caution. However, these cells or their descendants are clearly important in regulating hematopoietic function and are therefore niche components.

Adipocytes

An observation that adipocyte-rich vertebrae in mice contained significantly fewer cycling HSPCs compared with adipocyte-poor thoracic vertebrae led to the discovery of their role in HSPC regulation. In a genetic mouse model of lipoatrophy (i.e., a condition with reduced adipocyte number), post-transplant hematopoietic recovery was accelerated, although a concomitant increase in trabecular bone could have contributed to this result. Subsequent studies have indicated that adipocytes are important for hematopoietic reconstitution after transplantation.[17]

Osteoclasts

Osteoclasts are BM-derived cells that are located in close proximity to stem cell-rich endosteum and play a critical role in bone remodeling. During stress and GCSF-induced mobilization, the activity of the osteoclasts increases and is accompanied by secretion of proteolytic enzymes and reduction in the endosteal niche components, as evidenced by downregulation of the osteopontin expression by the OLCs. Conversely, inhibition of the osteoclasts leads to reduced HSPC and progenitor egress.

Bone Marrow Macrophages

During experiments investigating the mechanisms of GCSF-induced HSPC mobilization, it was noted that in addition to previously reported reduction in the endosteal OLCs, BM macrophages were also decreased in number. In vivo depletion of this cell population by clodronate administration produced the same result. It therefore appears that macrophages play a critical role in supporting the OLC niche compartment. A similar role for the macrophages, but with regard to supporting nestin-GFP^{low} MSCs, has been suggested by another study that used clodronate-mediated macrophage ablation. Again, this resulted in HSPC egress from the BM, perhaps through the effect on nestin-GFP^{low}, that showed a marked downregulation of genes responsible for HSPC retention in the niche (see earlier discussion). Thus, macrophages appear to function at a level of regulation upstream of OLCs and nestin-GFP^{low} cells.

Megakaryocytes

Megakaryocytes are the most recent addition to a growing list of niche cell types and appear to be directly involved in the regulation of HSPC quiescence, as shown by cell deletion studies.[18] This effect is mediated by CXCL4, also known as platelet factor 4, and TGF-beta. Overall, only 20% of immunophenotypically defined HSPCs are associated with megakaryocytes and were spatially distinct from HSPCs that are located near the arterioles, suggesting the existence of a specific megakaryocytic niche. The presented findings also illustrate a feedback mechanism, by which mature hematopoietic cells may regulate HSPC number.

EXTRINSIC REGULATION OF THE HEMATOPOIETIC STEM CELL NICHE

Sympathetic Innervation

Sensory and autonomic innervation of the BM is critical for its ability to respond to hematopoietic stress. Increase in sympathetic tone promotes HSPC mobilization and down-regulates the components of the endosteal niche, mainly through the activation of β_2-adrenergic receptor.[19] Nestin-positive cells express both β_2 and β_3 receptors and act as another mediator between sympathetic signaling and HSPCs, again facilitating egress from the BM. In a mouse model of streptozocin-induced diabetes, diabetic autonomic dysfunction was shown to disrupt this regulatory circuit, alter the function of Nestin-positive cells, and lead to impaired GCSF-induced HSPC mobilization, providing a biologic explanation for a higher frequency of peripheral blood stem cell mobilization failure in diabetic patients. The sympathetic nervous system is also involved in the regulation of HSPC egress from the BM as governed by circadian rhythms, a remarkable discovery based on a chance observation that continuous exposure to light (because of a broken light switch in the animal house) significantly altered the number of HSPCs mobilized after GCSF administration. Thus, sympathetic niche innervation is essential for relaying and integrating extrinsic signals and acts as a responsive and finely tuned tool that regulates HSPC traffic between peripheral blood and the BM. It is also now apparent that the loss of adrenergic innervation contributes to the changing function of the niche with aging.

Not only sympathetic nerves, but the glial cells that surround them can regulate HSPC behavior in the marrow, as exemplified by the studies of non-myelinating Schwann cells. These cells ensheath sympathetic nerves, come into contact with HSPCs, and are responsible for activation of the latent form of TGF-beta. Denervation experiments lead to a significant reduction in the number of glial cells and the associated increase in HSPC cycling.

Hypoxia

The niche for quiescent HSPCs is thought to be hypoxic. These observations are based on studies that use an intracellular marker of reducing equivalents, pimonidazole, or direct measurement of oxygen tension in the BM using intravital microscopy. By direct measurement of oxygen, it is apparent that the absolute level of Po_2 in the BM is quite low (less than 32 mmHg) and reduces to ~10 mmHg deeper into the marrow space.[20] The vascular network in the marrow is extensive, and it appears that the low Po_2 levels reflect high consumption by the action of hematopoiesis.

Hypoxia is associated with upregulation of stromal cell-derived factor 1 (SDF-1) expression in the endosteal region and HSPC traffic to the BM; in contrast, hyperbaric oxygen (exposure to 100% oxygen under increased atmospheric pressure) mobilizes HSPC and progenitors away from the BM. Hypoxic responses in the HSPCs are mediated through a family of hypoxia-inducible factors (HIFs). The best-studied species of HIFs is HIF1-α, inducing SDF-1 expression and directing metabolic circuits within HSPCs toward anaerobic metabolism. HIF1-α also stimulates secretion of VEGF, thereby promoting bone formation and angiogenesis. HIF1a affects HSPC function, as HIF1a deletion from HSPCs leads to HSPC exhaustion.

What is a physiologic role of hypoxia? First, hypoxia is believed to protect HSPCs in the niche from oxidative stress. Indeed, HSPCs within the niche contain a lower level of reactive oxygen species. Moreover, it appears that hypoxic conditions are beneficial for the HSPC function because culturing human BM HSPCs under lower oxygen tension leads to an increase in their ability to engraft and repopulate nonobese diabetic/severe combined immune-deficient (NOD/SCI) mice. Finally, hypoxia may also protect the HSPC pool from exhaustion by promoting cell cycle quiescence. Of note, when radiation or cytotoxic chemotherapy are used, the Po_2 levels in marrow go dramatically higher raising the question of whether Po_2 levels participate in the hematopoietic regenerative response to injury.

LYMPHOID NICHES

BM is the site of *B-cell lymphopoiesis*. Several cell types involved in the HSPC niche also participate in the formation of the lymphoid niches.[11] Interestingly, B-cell niches correspond to maturation stages of the lymphoid cells—OLCs, osteoclasts, and CAR cells are necessary for the less mature stages of development, whereas interleukin-7 (IL-7) secreting cells and sinusoidal endothelial cells are important for more differentiated cells. These observations come from targeted deletion of each supporting cell population using genetic means and analyzing the effect on B-cell homeostasis. For example, deletion of the OLCs leads to a considerable decrease in pre-pro and pro-B cells. This process appears to be mediated by the heterotrimeric G protein α subunit because its deletion in the OLCs leads to a 60% decrease in the percentage of B-cell precursors in the BM. A similar phenotype is seen upon the deletion of CAR cells.

Naïve recirculating B and T cells are located in the perisinusoidal space and co-localize with dendritic cells, which are thought to deliver supportive signals, because their deletion leads to a significant decrease in B-cell number and reduction in IgM production after immunization.

Plasma cells are the product of the terminal differentiation of B cells after antigen exposure. In vitro and in vivo studies showed that plasma cells receive multiple extrinsic survival signals, including CXCL12, IL-6, BAFF (B-cell activating factor of the TNF family), and APRIL (a proliferation-inducing ligand), which may account for their longevity. Mice deficient in CXCR4 displayed impaired homing of plasmablasts, illustrating the involvement of CXCL12–CXCR4 axis in plasma cell trafficking. Eosinophil- and megakaryocyte-derived APRIL and BAFF appear to regulate the number of plasma cells, which is greatly reduced upon eosinophil or megakaryocyte deletion.

The majority of long-lived *memory T cells* reside in the BM and appear to require a close contact with IL-7 secreting stromal cells to ensure that they remain quiescent in the absence of antigen stimulation. The BM also contains a large proportion of *regulatory T cells*, which have recently been found to exclusively protect HSPCs and early progenitors from rejection after allogeneic transplantation, arguing that the endosteal surface act as an immune-privileged site. Surprisingly, BM harbors specific niche cells (osteocalcin+ OLCs) that provide instructive cues to T-competent progenitors that migrate from the BM to the thymus since deletion of the osteocalcin-expressing cells leads to decreased intrathymic T-cell precursors and impaired generation of mature T-cells in the presence of normal thymic function.[21] Specific OLCs therefore appear to be important in T-lymphopoiesis. Their damage in the settings of conditioning for transplantation or graft-versus-host disease may compromise the ability of BM to provide the early T-lineage cells for thymocyte and ultimately, T-cell production.

ERYTHROID NICHES

Erythroblastic islands were first described by a French hematologist Marcel Bessis more than 50 years ago and consist of developing erythroblasts surrounding a central macrophage. They are present in the BM, fetal liver, and the spleen and in in vitro long-term BM cultures. The number of erythroblasts per island ranges from 10 cells observed in sections of rat femur to 5 to 30 erythroblasts seen in human BM. Some islands are located adjacent to the BM sinusoids, and the others are scattered throughout the BM cavity. Within erythroid islands, the macrophage functions as a "nurse cell" providing iron to the developing erythroblasts and phagocytosing the extruded nuclei at the end of erythroid differentiation.

Adhesion between maturing erythroblasts and central macrophage is mediated by several molecules, including erythroblast macrophage protein (Emp via homophilic binding), α4β1 integrin (VCAM-1), and αv integrin (ICAM-4); antibody-mediated blockade of each of these molecule results in disruption of the islands. The most striking effect is seen with the blockade of Emp, which causes significant increase in proliferation, maturation, and apoptosis of maturing erythroblasts in vitro. Of note, Emp-null fetuses die in utero from severe anemia.

In addition to interaction within macrophages, maturing erythroblasts adhere to extracellular matrix proteins, fibronectin, and laminin for the maturation to proceed. Fibronectin protects erythroblasts from apoptosis, partly through anti-apoptotic bcl-xL, and laminin is thought to localize reticulocytes to sinusoids as the initial step before their release into circulation.

MEGAKARYOCYTIC NICHES

Megakaryocytes localize to BM endothelial cells in vivo and release platelets into the marrow intravascular–sinusoidal space or the lung capillaries. Although CXCL12 induces platelet production by megakaryocytes if preceded by migration through endothelial cells, this is not observed in the absence of endothelial cells, suggesting that megakaryocyte interaction with specific molecules present on the endothelial cells is necessary for thrombopoiesis. FGF4 and CXCL12 enhance the interaction of megakaryocytes with endothelial cells and restore thrombopoiesis in mice deficient in thrombopoietin or its receptor c-mpl. Thus, chemokine-mediated localization of megakaryocytes within a specific vascular microenvironment is necessary for their maturation and platelet production. Notably, the pulmonary vascular tree also appears to be a site where megakaryocyte production of platelets occurs.[22]

HUMAN BONE MARROW MICROENVIRONMENT

Because direct mechanistic studies of the human BM microenvironment cannot be undertaken, the bulk of our knowledge comes from experiments in xenotransplantation models. These initially involved fetal sheep and heavily irradiated or nude mice as recipients, but only a very low level of human hematopoietic engraftment was observed. The discovery of SCID mice led to the development of two powerful models. The first, known as SCID-hu mouse, was generated by engrafting the human thymus and fetal liver. This model was most informative for the study of human lymphoid development and used for testing novel HIV drugs. The second model, hu-SRC (for SCID-repopulating cell), through the pioneering work of John Dick and colleagues, enabled the investigation of human HSPC engraftment and differentiation. Further modifications of the SCID model led to the generation of a NOD/SCID–IL2 receptor γ chain knock-out (NSG) strain, which supports robust normal human multilineage (myeloid and lymphoid) hematopoietic engraftment, as well as engraftment of acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL) cells from patients. The sensitivity of the transplant assay is further increased by direct intrafemoral injection into the BM cavity; remarkably, in NSG recipients, human hematopoietic engraftment can be detected after the intrafemoral transplantation of a single highly purified human HSPC. Further advances in the field of xenotransplantation is the development of mouse strains that express several human hematopoietic cytokines, thereby enabling support of innate immune cells (myeloid and NK cells). Several further iterations of the model are now available to permit the engraftment of human HSPC without conditioning.

Similar to mouse HSPCs, human HSPCs transplanted into mouse recipients preferentially traffic to the trabecular bone and home next to the endosteal surface. They are guided to their niches by the CXCL12–CXCR4 pathway and cell adhesion molecules such as very late antigen-4 (VLA-4), very late antigen-5 (VLA-5), and lymphocyte function-associated antigen-1 LFA-1; of note, CXCL12 is expressed by human OLCs, mesenchymal stromal, Nestin-positive, and endothelial cells. CD44 and hyaluronic acid cooperate with CXCL12 in human HSPC homing. Recent experiments identified α6 integrin CD49f as a novel marker for human HSPCs, alluding to the functional importance of HSPC anchorage within the BM microenvironment.

The cellular components of the human HSPC niche are yet to be identified, although single-cell cataloging of cell types has been conducted. One potential functional candidate is a population of mesenchymal subendothelial cells expressing CD146, which can be prospectively isolated from human BM. These perivascular cells were able to establish both bone and hematopoietic microenvironment upon subcutaneous transplantation; had a documented self-renewal capacity; and produced angiopoietin 1, a cytokine known to induce HSPC quiescence. CD271 has been suggested as another marker for the human hematopoiesis-supporting mesenchymal population; in addition to CD146+ perivascular cells, it labels CD146-endosteal population, which co-localizes with hematopoietic CD34+ cells in human BM.

The limitations of our knowledge of the human hematopoietic microenvironment restrict our ability to accomplish in vitro stem cell expansion. The potential benefits of doing so are especially evident in the context of cord blood transplantation when the number of donor cells is small and in the setting of gene-modified stem cells where gene transduction efficiencies are low. Several molecules have been tested. One of them is the sonic hedgehog protein, which has been shown to induce proliferation of primitive human hematopoietic cells when added to highly purified CD34+ CD38-lineage human cells; this effect translated into an increased level of progenitor expansion in NOD/SCID mice. The aryl hydrocarbon receptor antagonist, SR-1 also appears to increase HSPC and has improved hematopoietic reconstitution with SR-1 expanded cord blood transplantation. An engineered Notch ligand Delta 1 and pleiotrophin have both been shown to increase HSPC. Prostaglandin E_2 enhances murine HSPC localization in the BM after brief in vitro exposure. This resulted in a twofold to threefold increase in the number of HSPCs compared with control (vehicle-exposed) cells. PGE2-treated cord blood cells appeared to accelerate neutrophil recovery in a Phase I clinical trial. Other methods for expanding HSPC ex vivo continue to be developed, but the use of cord blood HSPC for transplant is declining, raising questions about the ultimate medical utility of expansion strategies.

HEMATOPOIETIC MICROENVIRONMENT IN ACUTE LEUKEMIA AND MYELODYSPLASIA

Given a critical role of the hematopoietic microenvironment in safeguarding cellular homeostasis in the BM, it is not surprising that alterations within it—either primary or induced by the presence of malignant cell population—have been proposed to contribute toward tumor initiation, maintenance, and resistance to treatment. Here, we summarize the data related to the role of the microenvironment in the pathogenesis of acute leukemia and myelodysplasia. For a review of this topic in other hematologic neoplasms, readers are referred to disease-specific chapters of this book.

Early in vitro studies alluded to the significant contribution of nonhematopoietic BM cells (collectively termed *stroma*) to the pathogenesis of acute leukemia. For example, fibroblastic stromal cells from patients with AML were unable to support normal granulocytic-macrophage colony formation in contrast to those obtained from normal individuals. However, when the stromal cells were tested from patients in remission, they maintained the growth of GM colonies similar to normal stroma. Strikingly, when the patients relapsed, this GM colony-supporting ability was lost. In another series of observations, when nonadherent cells from continuous marrow cultures or GM-CSF–dependent progenitor cell lines were co-cultured with mouse stromal cells that had been previously irradiated, they developed factor-independence and multiple distinct karyotypic abnormalities; upon subcutaneous injection, these newly transformed cell lines produced granulocytic monomyeloid tumors that spread to the spleen, lymph nodes, and BM. Although by no means definitive, these studies suggested that either the altered stromal cells may contribute to the emergence of leukemia, or leukemia itself may affect the nonhematopoietic compartment. Both of these hypotheses found confirmation in the later studies reviewed in the following sections.

Niche Contribution to Leukemia Development

The idea of "niche-induced oncogenesis," or contribution of the microenvironment to the emergence of malignant disease, stems from the clinical observation of donor-induced leukemia. In this condition, which has a reported incidence between 0.12% and 5%, the leukemic clone arises from an apparently normal donor hematopoietic cells after allogeneic BM transplantation. Although the etiology is clearly multifactorial, damage to the BM microenvironment, either because of previous chemotherapy or pre-transplant conditioning, may be an important contributing factor. In keeping with this notion, several experimental mouse models illustrate that microenvironmental alterations, either alone or in conjunction with corresponding molecular lesions in the hematopoietic compartment, can play a critical role in the initiation of malignant disease. For example, the mice with deficiency of phosphatase and tensin homolog (PTEN) both in the microenvironment and HSPC developed a myeloproliferative disorder, but PTEN deficiency in HSPCs alone did not result in the disease. Similarly, widespread deletion of retinoblastoma protein or retinoic acid receptor led to the development of myeloproliferative disorder, in the latter case purely because of gene deletion in the microenvironment. Using a cell type-specific approach, it was found that targeted deletion of the micro-RNA processing enzyme Dicer-1 in immature OLCs resulted in the development of myelodysplasia and acute leukemia associated with independent complex genetic changes.[23] The effect of Dicer-1 deletion was entirely attributable to the microenvironment because transplantation of Dicer 1-deleted BM into normal microenvironment resulted in reversal of the myelodysplastic phenotype. Remarkably, hematopoietic abnormalities were observed when Dicer-1 was deleted in very immature OLCs (osterix+) but not in those at a more mature differentiation stage (osteocalcin+). Deletion of the Schwachman-Diamond-Bodian syndrome gene in immature OLCs recapitulated the key features of the Dicer-1 deletion phenotype and implicated their role in its pathogenesis. In another striking example of niche involvement in leukemia generation, mice carrying an OLC-specific mutation of constitutively activated beta-catenin developed AML. The leukemic process was microenvironment-dependent and mediated by Notch signaling. Genetic or pharmacological inhibition of Notch signaling leads to a reversal of the leukemic phenotype. The findings of this study are clinically relevant, as 38% of patients with MDS and AML showed nuclear (activated) beta-catenin in osteoblasts.

Altogether, the presented studies illustrate that the perturbed BM microenvironment can act as a source of signals that promote malignant change in the hematopoietic compartment and highlight their potential role as therapeutic targets.

Niche Alterations by Leukemia

Just as the microenvironment can contribute to disordered hematopoiesis, it can be disrupted and modified by leukemic cells, leading to a competitive advantage over normal counterparts.[14,24,25]

Visualization of BM niches by intravital microscopy studies revealed that primary ALL and AML blasts are able to down regulate CXCL12 expression in the BM, causing the egress of normal CD34+ HSPCs from the BM and impairment of normal hematopoiesis. This process was mediated by the SCF secreted by leukemic blasts and reversed upon SCF neutralization. Similarly, in myeloproliferative disorders such as CML, it is thought that microenvironmental changes that are induced by malignant cells result in the formation of a self-reinforcing loop leading to preferential expansion of leukemic cells at the expense of their normal counterparts. Leukemia can also affect the niches indirectly, i.e., through perturbation of sympathetic innervation: both in CML and AML, "sympathetic neuropathy" promotes leukemogenesis through either reduction in quiescence-inducing nestin+ cells or altering their differentiation properties and frequency relative to nestin-GFP^{high}/NG2+ cells.[25] The "niche-modifying" ability of the leukemic cells in vivo is an area of ongoing investigation because it suggests that the leukemic niche can be molecularly distinct from the normal, thus creating an opportunity to alter the leukemic niche as a means of reducing the persistence of leukemia-initiating cells.

Therapeutic Targeting of Leukemic Niche

The CXCR4–CXCL12 pathway is critical for homing and subsequent adhesion of not only normal, but leukemic stem cells (LCSs) to the BM microenvironment. Of note, the level of CXCR4 is elevated in patients with AML and is associated with a poor outcome. The presence of Flt3 internal tandem duplication (a poor prognostic factor in AML) is in turn associated with increased CXCR4 expression. Experimentally, treatment of NOD/SCID mice transplanted with primary human AML cells using a neutralizing antibody against CXCR4 reduced the leukemic burden. Follow-up studies confirmed the antileukemic effect of blocking the CXCL12–CXCR4 axis using competitive antagonists of CXCR4 (AMD3100 and AMD3254) in mouse models of AML. These findings formed the basis for ongoing clinical trials of CXCR4 antagonist AMD3100 (Plerixafor) as a chemosensitizing agent in AML. So far, these studies have confirmed the safety and tolerability of this drug in combination with chemotherapy, but the effect on response rate and survival has not been demonstrated.

Another example of LSC niche dependence is a cell adhesion molecule CD44, which is present on the surface of leukemic cells and interacts with hyaluronan on the endosteal surface. Blocking the interaction between CD44 and hyaluronan using activating CD44 antibodies had a significant effect on LSC eradication and even cured some mice. The therapeutic effect of the antibody was more marked when it was administered soon after the injection of human leukemic cells compared with the animals with established disease, suggesting that it acts predominantly at the stage when LCSs engage their respective niches. It is also possible that some of the effect of the CD44 antibody was attributable to differentiation induction in the LSCs. Nevertheless, this study provided a proof-of-principle demonstration that LSCs interaction with the niche is required for their survival and leukemia progression and thereby raised the potential for targeting therapy.

Other molecular mediators of the LSC–microenvironment interaction have also been identified. B4 integrin (also known as very late antigen 4) mediates lodgment of leukemic cells in the BM and interacts with fibronectin to confer resistance to cytosine arabinoside-induced apoptosis. Integrin ligation triggers prosurvival pathways, and the blocking antibody leads to a reduction in the level of leukemic burden and a modest prolongation of the lifespan in human AML-transplanted animals. A similar protective role for AML blasts has been observed for β1 and β2 integrins. IL-3 receptor α chain (CD123) also contributes to LSC survival, at least partly through being involved in controlling LSC homing to the BM; the CD123 blocking antibody demonstrated considerable antileukemic activity, which was also attributable to promoting immune-mediating destruction of leukemic cells. This idea that has been explored further in the studies of blocking a macrophage-associated molecule CD47. Expression of CD47 on LSCs appears to protect the LSCs from phagocytosis. CD47 expression is associated with Flt3-ITD mutation and independently predicts worse prognosis. Mechanistically, CD47 acts as a "do not eat me" signal for the macrophages. Blocking CD47 antibody produces depletion of AML and MDS cells in human clinical trials in xenotransplantation models and specific eradication of LSCs. Phase 1 study of CD47 antibody in hematological malignancies and solid tumors is ongoing.

It has also been noted that leukemia induces a reorganization of the BM vasculature and that compromises normal HSPC support. Abrogating the vascular effects with deferoxamine was shown in mice to lead to improved normal hematopoiesis and responsiveness of AML to chemotherapy, resulting in improved survival.[26]

The innervation of the BM also contributes to leukemia. There is a loss of adrenergic stimulation that remodels the stroma to enhance AML growth; this appears to be mediated by the beta3 adrenergic receptor.[25] Further, metabolic changes in stromal cells contribute to sustaining AML cell survival, particularly during chemotherapy. A broad range of changes therefore accompany leukemia in the marrow; some may be primary, fostering leukemia induction, while others are secondary, fostering leukemic cell growth while compromising normal hematopoiesis.[27,28] Targeting these interactions may offer complementary therapies to those that are leukemia cell specific and certainly expand strategic considerations beyond that of leukemia cells themselves.

FUTURE DIRECTIONS

Although the concept of a specific microenvironment for different hematopoietic compartments was first proposed more than 100 years ago, it was not until recently that the existence of the "niches" has been experimentally proven and the molecular factors involved in cellular interactions have been discovered.

Our current knowledge of the hematopoietic microenvironment has been evolving in parallel and often leading that in other stem cell systems. It appears that fundamental components and molecular pathways are highly conserved among evolutionary diverse species, although their role in specific niches may vary. These include supporting stromal cells secreting soluble molecules regulating stem cell self-renewal (bone morphogenic protein and Wnt signaling), extracellular matrix proteins that serve as stem cell anchors (integrin ligands), blood vessels that are responsible for nutritional support and transit of stem cells in and away from the niche, and neural inputs for integrating signals from different systems. It is therefore likely that future studies in the spatial and molecular organization of other stem cell niches will inform the knowledge of hematopoietic niches and vice versa.

With a rapidly increasing number of cell types known to be involved in hematopoietic niches (and the number of different cytokines they produce, which will inevitably follow), it will be important to use a "network" approach—similar to the one used for the analysis of transcriptional networks—to understand how these multiple factors act in concert to control location, proliferation, and trafficking of HSPCs and more mature cells in the BM. It is possible that these factors work in a combinatorial manner, ultimately creating a "niche code" that is designed to suit a specific physiologic situation.

A particularly notable development over the recent years has been our improvement in understanding the role of the microenvironment in the initiation and maintenance of malignant disease, although many questions remain. We still know very little about the molecular mediators of "niche-induced oncogenesis" and those involved in microenvironment-induced chemoresistance. Recent advances in xenotransplantation assay using highly immunocompromised mouse strains for the study of normal and leukemic hematopoiesis, together with further molecular insights into the biology of LCSs, will provide an opportunity to address these issues.

Therapeutic manipulation of the hematopoietic microenvironment remains an ultimate goal of ongoing research. Clearly, the effort of the next several years will be focused on translating the wealth of data obtained from the animal models into human biology and the clinic. This work has already started with the clinical trials of ex vivo HSPC expansion before cord blood transplantation. A number of clinical trials are also underway to examine the efficacy of niche-directed therapies in hematologic malignancies. Although the animal data suggest that targeting the niche alone is often insufficient to achieve cure, especially in established disease, this approach has been successful in regaining leukemia chemosensitivity to commonly used agents and may become a valuable component of future treatment protocols, particularly in the setting of low tumor burden, such as minimal residual disease. Gaining a deeper insight into the molecular distinctions between normal and malignant niches will enable a better understanding of "niche competition" between normal and leukemic populations and lead to the development of novel approaches based on eradication of leukemic cells and fostering normal hematopoiesis through the manipulation of niche-derived signals.

CHAPTER 15

CELL ADHESION

Rodger P. McEver, Pilar Alcaide, and Francis W. Luscinskas

Cell adhesion is essential for the development and maintenance of multicellular organisms. Cell-to-cell and cell-to-matrix adhesion provide a mechanism for intercellular communication and to define the three-dimensional architecture of organs. The regulated nature of cell adhesion is particularly evident in the hematopoietic system, where blood cells routinely make transitions between nonadherent and adherent phenotypes during differentiation, and in response to stimuli in the circulation or extravascular space.

In the bone marrow (BM), hematopoietic stem cells reside in a specialized microenvironment called the *stem cell niche*, and their proliferation and differentiation are controlled not only by soluble growth factors but also by adhesion to stromal cells and matrix molecules (see Chapters 14 and 16 for more detailed discussion). Weakening of these adhesive interactions is required for mature blood cells to enter the circulation. Circulating erythrocytes normally remain nonadhesive until they become senescent and are finally cleared by the reticuloendothelial system (see Chapter 34 for more discussion). Other circulating blood cells often participate in regulated adhesive events during their lifespan. For example, prothymocytes adhere to thymic stromal cells where they undergo guided movement from the cortex to the medulla during maturation before reentering the circulation (see Chapter 24 for details of T cell development). T cells regularly adhere to the specialized high endothelial venules of lymph nodes in tissues, migrate into these organs for the sampling of processed antigens, and then exit via the lymphatics to recirculate in the blood (see Chapter 12 for more discussion). During inflammation, specific classes of leukocytes roll at very low velocity on acutely or chronically stimulated endothelium that line blood vessels, then adhere more tightly, and finally emigrate between endothelial cells into the tissues. There, neutrophils and monocytes phagocytose invading pathogens, and lymphocytes adhere to antigen-presenting cells, such as dendritic cells, B cells, and macrophages (see Chapter 123 for more discussion). During hemorrhage, platelets adhere to exposed subendothelial matrix components, spread, and recruit additional platelets into large aggregates that serve as an efficient surface for thrombin and fibrin generation. This is discussed in more detail later in Chapter 121. Leukocytes also adhere to activated platelets and to other leukocytes, and platelets also roll on the endothelium. When activated, endothelial cells increase the expression of molecules that affect the adhesiveness of platelets or leukocytes. Tight contacts between adjacent endothelial cells also regulate access of blood cells to the underlying tissues and passage of plasma proteins and fluid (edema).

ADHESION MOLECULES

Cells adhere through noncovalent bond formation between macromolecules on cell surfaces with macromolecules on other cell surfaces or in the extracellular matrix (ECM). These interactions involve either protein–protein or protein–carbohydrate recognition. Although some adhesion molecules are expressed only by blood or endothelial cells, most also are synthesized by other cells. Many adhesion molecules can be grouped into families according to related structural and functional features.

EXTRACELLULAR MATRIX PROTEINS

The ECM provides structural and mechanical support for many tissues and spatial cues that enable cell–cell communication and signaling. The principal constituents of the ECM are adhesive proteins and proteoglycans. The major proteins are collagens, von Willebrand factor (vWF), thrombospondins, elastin, fibronectin, laminin, and vitronectin. These proteins are large and often highly extended and consist of multiple domains with different binding functions. In some proteins such as fibronectin, alternative splicing can increase diversity by producing molecules with variable numbers of domains. In addition, stretching of fibronectin can expose cryptic binding sites. The many binding domains allow adhesive proteins to interact with each other as well as with cell-surface receptors, resulting in multipoint contacts that stabilize matrix structure. One adhesive protein, fibrinogen, is found predominantly in plasma but also may be deposited in the exposed subendothelial matrix after vascular injury. Fibronectin, vitronectin, thrombospondins, and vWF are located predominantly in the ECM but also are found in plasma in lower amounts. Several adhesive proteins also are stored in intracellular α-granules of platelets, where they are secreted after platelet activation at sites of vascular injury. Similarly, the endothelium stores adhesive proteins in cytoplasmic storage granules, called *Weibel–Palade bodies*, that are released upon injury or activation.

Proteoglycans contain protein cores to which are covalently attached many glycosaminoglycans—long linear polymers of repeating disaccharides. Most proteoglycans are in the ECM, but some are anchored on cell surfaces through a core protein that contains a membrane-spanning domain. Hyaluronan is a unique glycosaminoglycan that forms polymers with molecular masses up to several million daltons that are not covalently attached to a protein. Hyaluronan forms noncovalent interactions with globular domains on the protein core of proteoglycans and with a small molecule called *link protein*. The resultant hyaluronan–proteoglycan complexes can become very large, contributing to the structural stability of the matrix and function as space fillers during embryonic development. Hyaluronan can also bind to cell-surface receptors and is also abundantly produced during wound healing.

INTEGRINS

Integrins are a broadly distributed group of cell-surface adhesion receptors that consist of noncovalently associated α- and β-subunits (Fig. 15.1 and Table 15.1). There are 18 α-chains and eight β-chains that pair in many, but not all, of the possible combinations. All blood cells have multiple different integrins. The four β2 integrins, each paired with a unique α-subunit, are expressed only by leukocytes, and the αIIbβ3 integrin (glycoprotein IIb–IIIa [GPIIb–IIIa]) is expressed only by megakaryocytes and platelets. Multidomain adhesive proteins of the ECM are ligands for many integrins. Integrins are unusual adhesion molecules because they usually reside in an inactive state on the cell surface until they receive an activating signal. Some integrins bind to specific domains of several different proteins, and some adhesive proteins bind to several different integrins. These interactions generally mediate cell–matrix and cell–cell adhesion. A unique feature of integrins is the transmission of signals in both directions across the cell plasma membrane. Integrin binding to matrix informs the interior of the cell (outside-in), and intracellular signals or conditions inside cells transmit signals outward (inside-out) that regulate binding to matrix or to adhesion receptors on the surface of adjacent cells. Force can also

Figure 15.1 SCHEMATIC DIAGRAMS OF SEVERAL TYPES OF CELL SURFACE ADHESION RECEPTORS. Integrins consist of noncovalently linked α- and β-subunits, both of which contribute to ligand binding. The platelet αIIbβ3 integrin is illustrated at *far left*. Ig-like receptors contain a variable number of Ig homology domains, of which some bind ligands and others extend the ligand-binding domains from the plasma membrane. Shown *second from left* is VCAM-1, which contains seven Ig domains; the two domains that bind to integrins are *shaded*. The platelet GPIb–IX–V complex, depicted in the *middle diagram*, consists of several leucine-rich protein subunits. CD44, illustrated next, contains an amino-terminal (*N*-terminal) domain that binds to hyaluronan. Each of the selectins contains an *N*-terminal carbohydrate-recognition domain that binds sialylated and fucosylated oligosaccharides on specific cell-surface GP ligands. Illustrated at the *far right* is P-selectin. *GP*, Glycoprotein; *Ig*, immunoglobulin; *VCAM-1*, vascular cell adhesion molecule-1.

TABLE 15.1 **Integrins on Blood Cells**

Integrin Designation	Other Name(s)	Expressed by	Ligand(s)	Function(s)
$\alpha_1\beta_1$	VLA-1	Leukocytes, other cells	Collagens, LM	Adhesion to ECM
$\alpha_2\beta_1$	VLA-2 GPIa/IIa	Leukocytes, platelets, other cells	Collagens, LM	Adhesion to ECM
$\alpha_3\beta_1$	VLA-3	Leukocytes, other cells	Collagens, LM, FN	Adhesion to ECM
$\alpha_4\beta_1$	VLA-4	Monocytes, lymphocytes, eosinophils	VCAM-1, FN	Adhesion to cells, ECM
$\alpha_5\beta_1$	VLA-5 GPIc/IIa	Leukocytes, platelets, other cells	FN	Adhesion to ECM
$\alpha_6\beta_1$	VLA-6 GPIc/IIa	Leukocytes, platelets, other cells	LM	Adhesion to ECM
$\alpha_9\beta_1$		Neutrophils	VCAM-1	Adhesion to ECs
$\alpha_L\beta_2$	LFA-1 CD11a/CD18	Leukocytes	ICAM-1, -2, -3	Leukocyte aggregation and adhesion
$\alpha_M\beta_2$	MAC-1 CR3 CD11b/CD18	Neutrophils, monocytes	ICAM-1, FIB, CR for iC3b	Neutrophil aggregation and adhesion to ECs
$\alpha_X\beta_2$	P150,95 CD11c/CD18	Neutrophils, monocytes	CR for iC3b	Adhesion to ECs
$\alpha_D\beta_2$	CD11d/CD18	Eosinophils, monocytes, lymphocytes	VCAM-1, ICAM-3	Adhesion to leukocytes and to ECs
$\alpha_{IIb}\beta_3$	GPIIb/IIIa	Platelets	FIB, FN, vWF, VN, TSP	Platelet adhesion and aggregation
$\alpha_V\beta_3$	VN receptor	Platelets, ECs	FIB, FN, vWF, VN, TSP, collagens	Platelet adhesion, angiogenesis
$\alpha_4\beta_7$	LPAM-1	Lymphocytes	VCAM-1, MAdCAM-1, FN	Lymphocyte adhesion to ECs and ECM

CR, Complement receptor; *EC*, endothelial cell; *ECM*, extracellular matrix; *FIB*, fibrinogen; *FN*, fibronectin; *GP*, glycoprotein; *LFA-1*, leukocyte function-associated antigen; *LM*, laminin; *LPAM-1*, lymphocyte Peyer patch adhesion molecule; *MAdCAM-1*, mucosal addressin cell adhesion molecule-1; *TSP*, thrombospondin; *VCAM-1*, vascular cell adhesion molecule-1; *VLA*, very late-appearing antigen; *VN*, vitronectin; *vWF*, von Willebrand factor.

regulate integrin adhesive function. The application of tension to integrins can increase ligand binding and a reduction in tension lessens integrin adhesiveness. Cell–cell interactions result from integrin recognition of cell-surface members of the immunoglobulin superfamily. Binding of fibrinogen to $\alpha\text{IIb}\beta3$ integrins on adjacent platelets creates a molecular bridge that promotes platelet aggregation (Fig. 15.2).

IMMUNOGLOBULIN-LIKE RECEPTORS

Immunoglobulin superfamily members contain a variable number of disulfide-stabilized motifs similar to those in antibodies, which are linked to transmembrane and cytoplasmic domains (Table 15.2; see also Fig. 15.1). The immunoglobulin-like motif provides a framework on which specific recognition structures for other proteins can be added. Some of these motifs also recognize glycoconjugates. The immunoglobulin-like molecules, intercellular adhesion molecule 1 and 2 (ICAM-1 and ICAM-2), and vascular cell adhesion molecule 1 (VCAM-1), expressed on endothelial cells, as well as ICAM-3, expressed on leukocytes, mediate cell–cell contact through recognition of specific integrins on leukocytes. ICAM-4, expressed on erythroid precursors, binds to integrins on stromal cells of BM, which may regulate erythropoiesis. ICAM-5 is restricted to neural tissues. The immunoglobulin-like GPVI on platelets promotes cell activation by binding to collagen in the subendothelial matrix exposed on damaged blood vessels. Interactions between immunoglobulin-like molecules help to mediate adhesion between T cells and antigen-presenting cells. Thus, whereas the immunoglobulin-like molecules CD8 and CD4 on T cells bind to the conserved membrane-proximal domains of class I and class II major histocompatibility complex (MHC) proteins, respectively, the α- and β-chains of the T-cell receptor (TCR) bind to the polymorphic antigen-presenting domain. In addition, the immunoglobulin-like proteins CD2 and CD28 on T cells bind to the immunoglobulin-like protein leukocyte function-associated antigen-3 (LFA-3) and B7-1 (CD80) and B7-2 (CD86), respectively, on antigen-presenting cells. The immunoglobulin-like receptor, platelet, and endothelial cell adhesion molecule-1 (PECAM-1; CD31) uses homotypical interactions to promote contacts between adjacent endothelial cells and to mediate transmigration of leukocytes across vascular endothelium (Fig. 15.3). The immunoglobulin-like junctional adhesion molecules (JAMs), expressed on endothelial and epithelial cells and leukocytes, regulate endothelial and epithelial cell junctions, paracellular permeability, and leukocyte trafficking between endothelial and epithelial cells by homotypical interactions or by heterotypical interactions with integrins. JAM-A, the founding member of this family, functions as a homodimer and transmits intracellular signals critical for its function in the regulation of endothelial and epithelial permeability.

OTHER ADHESION RECEPTORS THAT MEDIATE PROTEIN–PROTEIN INTERACTIONS

Cadherins are cytoskeletal-linked type 1 transmembrane proteins that mediate calcium-dependent, cell-to-cell contact in many organs through homotypical binding to cadherins on adjacent cells (Table 15.3). Cadherins are found on endothelial cells, where they form adherens junctions and regulate permeability and leukocyte migration across endothelial cell-to-cell borders, termed *diapedesis* or *transendothelial migration*. Cadherins are also expressed in the epithelium and help form cell-to-cell junctions.

The GPIb–IX–V complex on platelets consists of leucine-rich protein subunits (see Figs. 15.1 and 15.2). Under conditions of high shear stress such as those found in arterial circulation, this complex promotes the initial platelet adhesion to injured vessels by binding to vWF exposed in the subendothelial matrix. It also assists interactions with other platelets or with endothelial cells by binding to P-selectin, which normally binds to glycoconjugates, and it may assist platelet adhesion to leukocytes by binding to the integrin $\alpha_m\beta_2$.

CD36 is a multifunctional receptor with at least two membrane-spanning domains that is expressed on many cell types. On platelets, it has been implicated as a receptor for collagen and for thrombospondin and as a receptor to activate NADPH oxidase and

TABLE 15.2 **Immunoglobulin-Like Receptors**

Name	Other Name	Expressed by	Ligand	Function(s)
ICAM-1		Macrophages, EC, other cells	$\alpha_M\beta_2$, $\alpha_L\beta_2$, FIB	T-cell responses, leukocyte adhesion to EC
ICAM-2		EC	$\alpha_L\beta_2$	Leukocyte adhesion to EC
ICAM-3		Leukocytes	$\alpha_L\beta_2$	T-cell responses, leukocyte aggregation
ICAM-4		Erythroid precursors	$\alpha_4\beta_1$, $\alpha_V\beta_3$, $\alpha_{IIb}\beta_3$	Regulate erythropoiesis
ICAM-5	Telencephalin	Telencephalic neurons	ICAM-5, $\alpha L\beta 2$, $\alpha 5\beta 1$	Neuron-neuron and neuron-leukocyte
GPVI		Platelets	Collagen	Platelet adhesion and activation
PECAM-1	CD31	Leukocytes, platelets, EC	PECAM-1	EC junctions, leukocyte transmigration, cell signaling
VCAM-1		Activated EC, smooth muscle cells	$\alpha_4\beta_1$, $\alpha_4\beta_7$	Mononuclear cell adhesion to EC
MAdCAM-1		EC of Peyer patches	$\alpha_4\beta_7$	Lymphocyte homing
Siglecs		Leukocyte subsets	Sialylated glycans	Regulates B-cell activation, innate immunity?, hematopoiesis?
JAMs		EC	JAMs, $\alpha_L\beta_2$, $\alpha_4\beta_1$	EC junctions, leukocyte transmigration
CD2		T cells	LFA-3[a]	T-cell responses
CD4		T cells	Class II MHC[a]	T-cell responses
CD8		T cells	Class I MHC[a]	T-cell responses
CD3	T-cell receptor	T cells	Antigen on MHC[a]	T-cell responses
CD28	Costimulatory molecule	T cells	CD80, CD86	T-cell responses

[a] LFA-3 and classes I and II MHC molecules are also immunoglobulin-like receptors.

ICAM-1, -2, -3, -4, Intercellular adhesion molecules; *JAM,* junctional adhesion molecule; *MHC,* major histocompatibility complex; *PECAM-1,* platelet and endothelial cell adhesion molecules-1. For other abbreviations, see Table 15.1 footnotes.

TABLE 15.3 Other Adhesion Receptors

Name	Other Name	Expressed by	Ligand	Function(s)
Cadherins		EC, many other cells	Homotypic binding	Formation of EC junctions
GPIb/IX/V		Platelets	vWF	Platelet adhesion to ECM under shear
CD36	GPIV	Platelets, many other cells	Collagens, TSP	Platelet adhesion to ECM
CD44		Leukocytes, other cells	Hyaluronan, serglycin	Lymphopoiesis, lymphocyte activation
DC-SIGN		Dendritic cells	Mannosylated glycans, other glycans	Regulate T-cell–dendritic cell interactions, recognize pathogens
NK cell receptors		NK cells	MHC molecules	Recognition of virus-infected or other foreign cells

DC-SIGN, Dendritic cell-specific ICAM-3 grabbing nonintegrin; *MHC*, major histocompatibility complex; *NK*, natural killer. For other abbreviations, see Table 15.1 footnotes.

TABLE 15.4 Selectins

Name	Other Name (s)	Expressed by	Ligand	Ligands Expressed by	Function(s)
P-selectin	CD62P GMP-140 PADGEM	Thrombin-activated platelets and ECs, cytokine-activated ECs	PSGL-1, GPIbα	Leukocytes, platelets	Leukocyte adhesion to activated ECs and platelets
E-selectin	CD62E ELAM-1	Cytokine-activated ECs	PSGL-1, other sialylated and fucosylated GPs	Leukocytes	Leukocyte adhesion to activated ECs
L-selectin	CD62L LECAM-1 LAM-1	Leukocytes	PSGL-1, also GlyCAM-1, CD34, and other mucins on ECs of lymph nodes	Leukocytes, ECs or lymph nodes	Leukocyte adhesion to other leukocytes; lymphocyte homing to lymph nodes

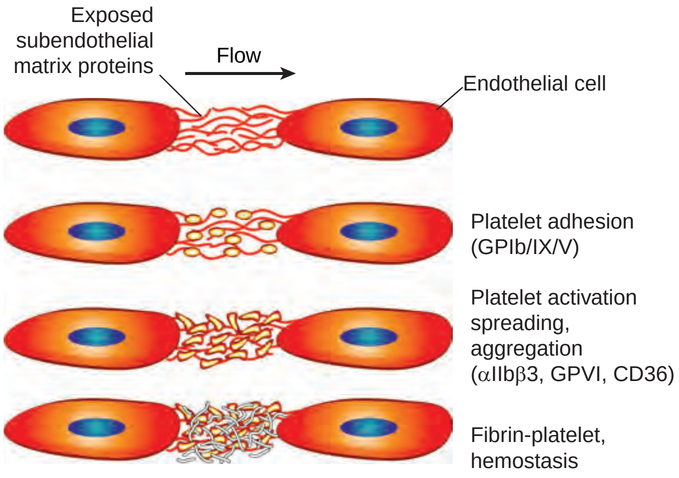
The selectins bind to sialylated, fucosylated, and (in some cases) sulfated oligosaccharides on specific glycoproteins, of which only some have been identified. *EC*, Endothelial cell; *ELAM-1*, endothelial leukocyte adhesion molecule-1; *Gly-CAM-1*, glycosylation-dependent cell adhesion molecule-1; *GMP-140*, granule membrane protein-140; *LAM-1*, leukocyte adhesion molecule-1; *LECAM-1*, leukocyte endothelial cell adhesion molecule-1; *PADGEM*, platelet activation-dependent granule external membrane protein; *PSGL-1*, P-selectin glycoprotein ligand-1. For other abbreviations, see Table 15.1 footnotes.

generate reactive oxygen species (ROS); both processes could facilitate adhesion and activation at sites of hemorrhage.

LECTIN ADHESION RECEPTORS

CD44 is an unusual transmembrane GP expressed to variable degrees on many subsets of leukocytes (see Fig. 15.1). It has a membrane-distal domain that is structurally related to the link protein of the ECM, and similar to link protein, CD44 can bind to hyaluronan. The hyaluronan-binding function of CD44 may modulate a number of leukocyte responses. The most clearly demonstrated function is in lymphopoiesis, where maturation of lymphocyte precursors requires contact with BM stromal cells bearing surface hyaluronan. CD44–hyaluronate interactions also may promote lymphocyte entry to and transit through organized lymphoid tissues. The membrane-proximal regions of CD44 are structurally diverse because of the insertion of variable numbers of domains through alternative splicing. These insertions may regulate the ability of CD44 to bind hyaluronan and may mediate post-binding events that affect cell signaling, proliferation, differentiation, and motility.

The selectins are a group of three receptors that terminate in a membrane-distal carbohydrate-recognition domain related to those in Ca^{2+}-dependent (C-type) animal lectins such as the hepatic asialoglycoprotein receptor (see Fig. 15.1). L-selectin is expressed on leukocytes, E-selectin on cytokine-activated endothelium, and P-selectin on macrophages, platelets, and endothelial cells exposed to secretagogues such as thrombin or histamine (Table 15.4). The selectins mediate leukocyte adhesion to platelets, endothelium, or other leukocytes through Ca^{2+}-dependent interactions of the carbohydrate-recognition domains with cell-surface carbohydrates on opposing cells (see Fig. 15.3). High-affinity binding appears to require specific carbohydrate structures



Exposed subendothelial matrix proteins

Endothelial cell
Platelet adhesion (GPIb/IX/V)
Platelet activation spreading, aggregation (αIIbβ3, GPVI, CD36)
Fibrin-platelet, hemostasis

Figure 15.2 PLATELET ADHESION, AGGREGATION, AND HEMOSTASIS. In response to arterial injury under high shear forces, platelets rapidly adhere to the subendothelial matrix of injured vessels. The initial contacts are made between GPIb–IX–V on platelets and von Willebrand factor (vWF) in the matrix. These molecular interactions help activate platelets, thereby increasing the affinity of several platelet integrins for other adhesive matrix proteins such as fibronectin, laminin, and collagens. GPVI further activates platelets by binding to collagen. CD36 also interacts with both collagen and thrombospondin. Fibrinogen cross-links activated platelets into aggregates by binding to $\alpha_{IIb}\beta_3$ integrins. The platelet plug then serves as an efficient surface for the generation of thrombin and fibrin. *GP*, Glycoprotein.

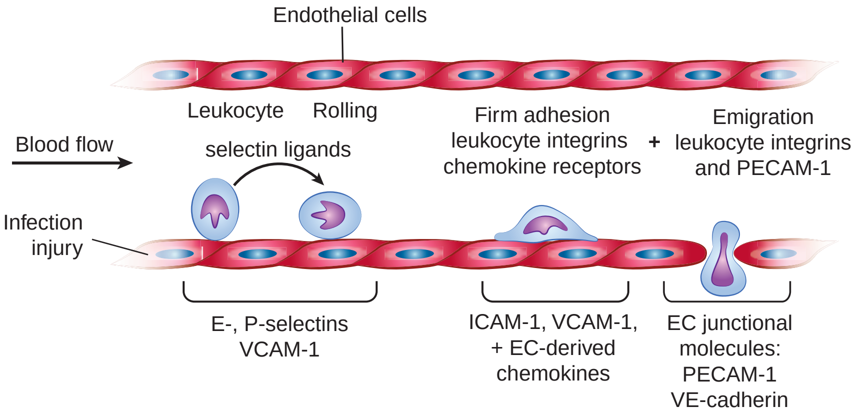

Figure 15.3 LEUKOCYTE ROLLING, SPREADING, AND EMIGRATION. At sites of tissue injury or infection, the vascular endothelium becomes hyperadhesive for leukocytes through activation by inflammatory cytokines tumor necrosis factor-α (TNF-α) or interleukin-1β (IL-1β), or by endotoxins (LPS). Leukocytes first roll on the activated endothelium in postcapillary venules. These transient adhesive interactions are mediated by TNF or LPS activation-induced transcription-dependent expression of E- or P-selectin and VCAM-1 on the endothelial cell surface. E- and P-selectin bind to glycosylated selectin ligands expressed on leukocytes and VCAM-1 binds VLA-4 integrins expressed by certain leukocytes. These molecular bonds can form under the shear forces in the venular circulation. The rolling leukocytes become activated by locally generated inflammatory mediators presented by endothelial cells that increase the affinity of β_2 integrins for intercellular adhesion molecule-1 (ICAM-1) on the endothelium. These bonds slow rolling and, in combination with endothelial-expressed chemokines, trigger firm adhesion to the endothelium. Leukocytes migrate to endothelial lateral borders and then through cell-cell borders by engaging adhesion molecules PECAM-1, CD99, CD47, ICAM-1, and others into tissues. *PECAM-1*, Platelet and endothelial cell adhesion molecule-1, CD31; *VCAM-1*, vascular cell adhesion molecule-1.

displayed on a limited number of membrane GPs. The best-characterized GP ligands for selectins are mucins, which have large numbers of clustered, sialylated *O*-linked oligosaccharides. Site-specific construction of *O*-glycans with specific sialylated, fucosylated, and (in some cases) sulfated moieties is required for these mucins to bind optimally to selectins. In the case of one mucin, P-selectin GP ligand-1 (PSGL-1), sulfation of tyrosine residues near a specific O-glycan is required for binding to P- and L-selectin.

Dendritic cells and related macrophages express a novel group of C-type lectins, of which the best characterized is dendritic cell-specific ICAM-3-grabbing nonintegrin (DC-SIGN). DC-SIGN binds to particular oligosaccharides on ICAMs, thereby regulating T-cell and dendritic cell function during antigen presentation. It also binds to glycans on a variety of pathogens, which may have critical roles in innate immunity. Natural killer cells express a different group of proteins, with some containing membrane-distal C-type lectin-like domains (e.g., NKG2D). Although these receptors are important for interactions of natural killer cells with target cells, they may bind to proteins rather than to glycoconjugates.

Siglecs are a subgroup of membrane proteins of the immunoglobulin superfamily that bind to carbohydrates instead of to proteins (see Table 15.2). The first two amino-terminal (*N*-terminal) domains appear to be necessary and sufficient for carbohydrate recognition. The *N*-terminal domain is a V-type structure that includes an unusual disulfide bond that is not found in the more common C-type immunoglobulin domains. Siglecs bind well to sialylated glycans on some but not all GPs. Different siglecs preferentially recognize sialic acid that is linked α2,6-, α2,8-, or α2,3- to an underlying galactose residue. Most siglecs have immune receptor tyrosine-based inhibitory motifs and transmit inhibitory signals. Siglecs can form *cis* interactions with other GPs on the same cell or *trans* interactions with GPs on another cell. The best-characterized example is CD22, which negatively regulates B-cell activation when it engages sialylated GPs. Sialoadhesin, expressed on BM macrophages, may regulate hematopoietic cell differentiation.

LIGAND BINDING VERSUS CELL ADHESION

As with all noncovalent macromolecular interactions, adhesion molecules bind to each other with equilibrium affinities defined by association and dissociation rates. However, the efficiency of cell adhesion is not simply a function of the solution-phase equilibrium affinities of adhesion molecules for one another. Adhesion molecules in cell membranes and matrices are limited primarily to two dimensions, and even low-affinity molecular interactions stabilize adhesion if there is time for sufficient bonds to form, or to cluster together along the plane of cell contact. The efficiency of cell attachment and the ensuing strength of adhesion reflect multiple factors that dictate the probability of formation of bonds between adhesion molecules on cell or matrix surfaces. The kinetics of bond formation and dissociation are especially important for certain kinds of cell adhesion. Furthermore, interactions between cell adhesion molecules are subjected to force, affecting the lifetimes of adhesive bonds. This is particularly true in circulation, where platelets and leukocytes must rapidly adhere to the blood vessel wall and withstand forces applied by the wall shear stresses of flowing blood. Other factors that affect bond formation include the number of adhesion molecules on a cell or matrix surface, the distance the binding domain of an adhesion receptor protrudes from the cell membrane, the lateral mobility of receptors, receptor dimerization, and the clustering of receptors on microvilli or other membrane domains. Cell adhesion can be further stabilized by events that occur after the initial interactions of adhesion molecules. For example, the cytoplasmic domains of many adhesion molecules bind to cytoskeletal components, allowing clustering of receptors into surface patches that strengthen adhesion, thereby promoting cell spreading or migration.

REGULATION OF ADHESION RECEPTORS

To prevent inappropriate interactions of cells with each other or with the ECM, the expression and function of adhesion receptors must be tightly controlled. Three primary control mechanisms are used: (1) the rate of synthesis of the receptor, (2) the time during which the receptor is displayed on the cell surface, and (3) the binding affinity or avidity of the receptor for ligands (Table 15.5).

REGULATION OF SYNTHESIS

The synthesis of many adhesion receptors is regulated. Erythroid precursors synthesize integrins that mediate their interactions with

TABLE 15.5 **Regulation of Adhesion Receptors**

Mechanism	Example
Synthesis	Erythroid precursor synthesis of $\alpha_5\beta_1$
	Lymphocyte synthesis of CD44
	Cytokine-induced synthesis of E-selectin, P-selectin, ICAM-1, and VCAM-1 by endothelial cells
Surface expression	Proteolytic cleavage of L-selectin from leukocytes
	Redistribution of P-selectin from granule membranes to plasma membrane of platelets and endothelial cells
	Endocytosis of P- and E-selectin on endothelial cells
Ligand affinity	Activation-induced increased affinity of many integrins for their ligands
	Activation-induced increased affinity of CD44 for hyaluronan

For abbreviations, see Table 15.1 footnotes.

stromal cells and with ECM in the BM. As the precursors mature, synthesis ceases, resulting in loss of expression of cell-surface integrins by the time a mature erythrocyte enters the circulation. Lymphocyte precursors synthesize CD44 during differentiation in the BM, stop synthesis before release, and resume synthesis during maturation in the thymus. On exposure to antigens, immunologically naïve lymphocytes synthesize increased amounts of several adhesion receptors and chemokine receptors during their conversion to the effector phenotypes; this process presumably allows these cells to become more adhesive in response to a subsequent antigenic challenge. Endothelial cells in postcapillary venules of the peripheral vasculature express very low, if any, levels of adhesion molecules that bind leukocytes. When exposed to inflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-1β(IL-1β) or bacterial endotoxins, endothelial cells transiently increase the synthesis of E- and P-selectin, ICAM-1, VCAM-1, and chemoattractants, resulting in a surface for leukocytes to adhere (see Fig. 15.3).

REGULATION OF SURFACE EXPRESSION

The surface expression of some adhesion receptors is tightly controlled. L-selectin is present on the plasma membrane of leukocytes, where it is available to bind to ligands on the endothelial cell surface. Stimulation of the leukocyte causes L-selectin to be shed into the plasma by proteolytic cleavage. P-selectin is constitutively synthesized by megakaryocytes (where it is incorporated into platelets) and by endothelial cells. Rather than being directly delivered to the plasma membrane, it is sorted into secretory storage granules: the α granules of platelets and the Weibel–Palade bodies of endothelial cells. On stimulation of these cells by agonists such as thrombin, P-selectin is rapidly transported to the cell surface during the fusion of granule membranes with the plasma membrane. When they are on the surface of the endothelium, both E-selectin and P-selectin are internalized and delivered to lysosomes for degradation. The net result of these events is to control the duration of exposure of E- and P-selectin on the endothelium, where they can mediate the adhesion of leukocytes. Activation of leukocytes also mobilizes a pool of $\alpha M\beta_2$ integrins from storage compartments to the plasma membrane, although some of these molecules are also constitutively expressed on the cell surface. Finally, platelet activation redistributes a portion of the GPIb–IX–V complexes from ligand-accessible positions on the plasma membrane to sequestered, invaginated membrane domains known as the *surface-connected canalicular system*. This process requires interactions of the cytoplasmic domain of GPIb–IX–V with the cytoskeleton and may serve to downregulate GPIb-mediated adhesion of platelets to immobilized vWF.

REGULATION OF BINDING AFFINITY

Regulation of binding affinity is an important control mechanism for other adhesion receptors. Many integrins are constitutively present on the cell surface but interact poorly with their ligands. Cell activation by a number of agonists induces conformational changes in integrins so that they effectively recognize their ligands. An example is the $\alpha_{IIb}\beta_3$ integrin, which requires platelet stimulation to bind fibrinogen; if this binding affinity were not regulated, circulating platelets would indiscriminately aggregate in the fibrinogen-rich plasma milieu. The cytoplasmic domains of integrins can exert both positive and negative influences on binding affinity. Binding of specific cytoplasmic proteins to these domains may propagate structural changes to the extracellular ligand-binding regions of the integrins. Three-dimensional structures of integrins suggest that the integrin "headpiece" that contains the ligand-binding site faces down toward the membrane in the inactive conformation and rapidly extends upward in a "switchblade"-like opening motion on activation. Low-affinity ligand binding may stabilize some active conformations of integrins, perhaps explaining why integrins on unactivated cells will sometimes bind to immobilized, multivalent adhesive proteins but not to the same proteins in solution. Cellular activation may also regulate the binding avidities of CD44, L-selectin, P-selectin, and some integrins through changes in membrane distribution engineered by interactions of their cytoplasmic domains with the cytoskeleton or with clathrin-coated pits.

CELL SIGNALING THROUGH ADHESION MOLECULES

In addition to their roles in cell–cell and cell–matrix contacts, adhesion molecules initiate cell signaling through indirect or direct mechanisms. Proteoglycans in the ECM can sequester growth factors that can be released to bind to surface receptors on nearby cells. Some chemoattractants, called chemokines, bind to proteoglycans on the surface of endothelial cells, where they can bind to G protein-coupled receptors (GPCRs) that activate rolling leukocytes (see Fig. 15.3). Binding of adhesive ligands to cell-surface integrins, GPIb–IX–V, CD44, cadherins, CD36, PECAM-1, selectins, ICAM-1, and VCAM-1, and perhaps other receptors can directly trigger intracellular events. The consequences of such signaling include changes in affinity or avidity of other adhesion receptors for their ligands, shape change, secretion, proliferation, synthesis of cytokines and other molecules, and migration. Most commonly, signaling requires cross-linking of several receptors through interactions with multivalent ligands in matrix or on opposing cells.

Many studies of adhesion receptor signaling have focused on integrins. Binding of the same ligand to different integrins can mediate different responses in the same cell. Furthermore, ligand binding to the same integrin expressed in different cells can result in different signals. These data suggest that very specific interactions occur between ligand-occupied integrins and intracellular components. The cytoplasmic domains of integrins are essential for initiating signaling. Tyrosine kinases have been localized at the interaction zones between integrins, the cytoskeleton and several adaptor and effector molecules, and tyrosine phosphorylation of a number of proteins accompanies integrin-mediated cell signaling. Tyrosine phosphorylation initiates a cascade of signaling events, including the activation of serine/threonine kinases, which cause a variety of cellular responses. Ligand binding to integrins also results in the generation of lipid second messengers, alkalization of the cytoplasm, and influxes of Ca^{2+}.

COOPERATIVE INTERACTIONS BETWEEN SIGNALING AND ADHESION MOLECULES

Signaling and adhesion molecules frequently function cooperatively in sequential cascades to enhance the specificity of cell adhesion. Three examples of how these cooperative interactions facilitate blood cell responses are described next.

Platelet Adhesion, Aggregation, and Hemostasis

At sites of blood vessel injury in the arterial circuit, platelets rapidly tether to and roll along the damaged vessel through reversible interactions of GPIb–IX–V receptors with immobilized vWF exposed in the subendothelial matrix of injured vessels (see Fig. 15.2). These interactions are facilitated by arterial flow and enabled by bond formation between GPIb and matrix vWF. An important feature of this initial reversible adhesive event is that prior activation of the platelets is not required. After adhesion, however, the interaction of immobilized vWF with GPIb receptors triggers intracellular signals that synergize with those produced by the engagement of collagen by its receptor GPVI. Platelet activation, in turn, further increases the affinity of platelet integrins for collagen and fibronectin in the exposed matrix to stabilize adhesion. Binding of these ligands transduces signals that propagate platelet spreading and secretion of granule contents that enhance the recruitment of additional platelets and leukocytes through cell–cell contact mediated by binding of fibrinogen to activated platelet $\alpha_{IIb}\beta_3$ and leukocyte αMβ2 integrins. This adhesion cascade allows unstimulated platelets and leukocytes to specifically recognize sites of vascular injury and then be activated by locally generated mediators.

Leukocyte Rolling, Spreading, and Migration Across Vascular Endothelium During Inflammation

Near sites of extravascular bacterial infections and injury, leukocytes first tether to and roll on the endothelial surface of postcapillary venules through the interactions of selectins with cell-surface carbohydrate ligands (see Fig. 15.3). Neutrophils are generally among the first leukocytes to exit the blood stream, are the most abundant in blood, and are the best studied in the different steps of the extravasation cascade. Little, if any, leukocyte adhesion occurs in nearby arterioles, except in specific disease conditions of the arterial vascular wall such as atherosclerosis. Leukocyte rolling on the endothelium occurs under shear forces, just as platelets adhere to subendothelial matrix under shear forces, although the shear flow in postcapillary venules is lower than that in arterioles. Rolling requires a balance between the formation of selectin–ligand bonds at the leading edge of the cell and the dissociation of bonds at the trailing edge of the cell. Whereas shear forces affect the lifetimes of selectin–ligand bonds, lower forces prolong lifetimes (catch bonds) and higher forces shorten lifetimes (slip bonds). Catch bonds help explain why a minimum shear force is required to support leukocyte rolling, particularly through L-selectin. Just as the initial adhesion to vWF does not require prior activation of platelets, selectin-mediated rolling does not require prior activation of leukocytes. Instead, locally generated inflammatory mediators induce expression of E- or P-selectin on the endothelial cell surface. The requirement for activation of endothelial cells rather than leukocytes allows the latter to adhere to vessels only at the site of vessel inflammation. Several infectious and sterile soluble mediators, such as endotoxins or pro-inflammatory cytokines, are involved in this critical step of endothelial cell activation that converts the endothelial anti-adhesive surface into a pro-adhesive surface, which expresses selectins and integrin ligands that interact with leukocyte selectin ligands and integrins. After being situated on the vessel wall through selectin-mediated contacts, however, the neutrophils become exposed to stimuli including a platelet-activating factor, a phospholipid signaling molecule, activated complement proteins, and chemokines like interleukin-8 (IL-8), which are presented on the surface of activated endothelial cells. These signals cooperate with others directed by engagement of selectin ligands and promote very slow rolling of neutrophils on the surface of activated endothelium. Neutrophil activation increases the affinity of β_2 integrins for immunoglobulin counterreceptors on the endothelial cell surface such as ICAM-1. Although flowing cells cannot form these bonds, leukocytes rolling on selectins can do so because of their slower velocities. The integrin–ICAM interactions further slow rolling and then arrest the cells near endothelial cell-to-cell junctions. The leukocytes then migrate, presumably because of disengagement of integrin–ICAM bonds and redistribution of integrins to the leading edge of the cell, where new bonds form. Interactions of leukocytes with endothelial cell junctional molecules such as PECAM-1, CD47, and other molecules facilitate transendothelial migration of the leukocytes into the underlying tissues. Adhesion of leukocytes to the endothelium disrupts cytoskeletal tethers to the endothelial cadherins; this disruption leads to dissociation of homotypical cadherin interactions that normally prevent the passage of leukocytes. Intracellular calcium in endothelial cells also contributes to leukocyte transendothelial migration during the integrin- and the PECAM-1–mediated adhesive events. These signals contribute to cytoskeletal redistributions in leukocytes and endothelial cells, which enhance leukocyte migr ation toward chemotactic molecules released in the vicinity of the infected or injured area. All of these steps are commonly shared by all leukocytes, although differences in responsiveness to certain chemokines and in expression/activation of adhesion molecules to mediate interactions with EC have been described. When leukocytes enter the tissues, integrin recognition of ECM protein ligands and inflammatory mediators, such as damage-associated molecular pattern molecules (DAMPs) and pathogen-associate pattern molecules (PAMPs), trigger secretion of proteolytic enzymes and production of ROS, cytokines, interferons, and chemokines that optimize bactericidal function.

Adhesion of T Cells to Antigen-Presenting Cells during Antigen Priming

The initial engagement of naïve T cells with antigen-presenting cells (APCs) requires that the TCR (αβ TCR) recognize antigen presented by the polymorphic domain of MHC molecules (Fig. 15.4). Subsequent interactions include the binding of CD8 or CD4 to MHC class I or II molecules, respectively. These molecular contacts are all of low affinity but are highly specific because they first require specific antigen presentation to the appropriate TCR. The combination of these binding events triggers inside-out signals that increase the affinity of LFA-1 ($\alpha_L\beta_2$), a β_2 integrin on T cells, for its ligand ICAM-1 on APCs, strengthening and prolonging the length of time cells stably adhere. During this time, the T cell is further activated by a second or costimulatory signal delivered by T-cell CD28 binding to CD80 and CD86 expressed by APCs. Together these interactions drive TCR-induced gene activation (interferon, chemokine, and cytokine production) and cell proliferation and differentiation into effector T cells that exit the secondary lymph node and migrate to immune reactions (see Chapter 24 for T cell-antigen priming).

The first principle of these three responses is that the initial adhesive event, although relatively limited, is highly specific. Thus, platelets bind to an exposed subendothelial matrix in injured vessels, neutrophils bind to activated endothelium at sites of infection, and T cells bind to antigen-loaded APC in secondary lymph nodes. The second principle is that subsequent activation events strengthen cell adhesion and lead to further responses such as secretion, fibrin formation, cellular migration, and release of mediators for cell activation and proliferation. Thus, adhesion and cell signaling are highly interrelated processes.

The process of reversing cell adhesion, although less well understood, is equally important for the control of cell behavior. Some molecules such as the selectins can be proteolytically cleaved or internalized. The activation-induced increases in the affinity of integrins

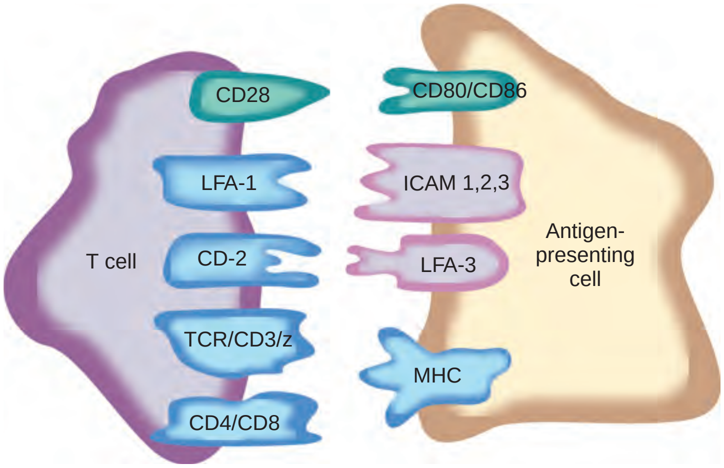

Figure 15.4 ADHESION BETWEEN T LYMPHOCYTES AND ANTIGEN-PRESENTING CELLS. The initial contact is mediated by the T-cell receptor (TCR) complex, composed of the TCR non-covalently linked to CD3 and ζ (z) proteins, which binds with low affinity but high specificity to a specific antigen peptide presented by an MHC molecule. Additional contacts, also of low affinity, are between CD4 (on helper cells) or CD8 (on cytotoxic cells) and MHC, between costimulatory molecules CD2 and LFA-3, and between CD28 with both CD80 (B7-1) and CD86 (B7-2). These interactions signal the T cell to transiently increase the affinity of its β_2 integrin LFA-1 for ICAM-1 on the antigen-presenting cell. These bonds strengthen adhesion, and the costimulatory molecules transduce sustained and additional signals to the T cell that causes increased gene transcription, proliferation, and cytokine secretion and produce effector and regulatory T cells. Not shown is the redistribution of these adhesion molecules into different regions of the contact zone as adhesion strengthens. *ICAM*, Intercellular adhesion molecule; *LFA-3*, leukocyte function-associated antigen-3; *MHC*, major histocompatibility complex.

TABLE 15.6 **Genetic Deficiencies in Adhesion Molecules**

Molecule	Disease	Laboratory Finding(s)	Clinical Finding(s)
$\alpha_{IIb}\beta_3$	Glanzmann thrombasthenia	Impaired platelet aggregation	Mucocutaneous bleeding
GPIb–IX–V	Bernard–Soulier syndrome	Impaired platelet adhesion to vWF	Mucocutaneous bleeding
β2 integrins	Leukocyte adhesion deficiency-1	Impaired adhesion of activated leukocytes to EC	Frequent infections
Selectin ligands	Leukocyte adhesion deficiency-2	Impaired fucose metabolism resulting in defective carbohydrate ligands for selectins, impaired rolling of leukocytes on venules	Frequent infections
β1, β2, β3 integrins	Leukocyte adhesion deficiency-3	Impaired platelet adhesion and aggregation and impaired adhesion of activated leukocytes to EC	Mucocutaneous bleeding and frequent infections

For abbreviations, see Table 15.1 footnotes.

and CD44 for their ligands are generally transient, but the mechanisms for return to the inactive conformation are obscure.

Genetic Deficiencies in Adhesion Molecules

Genetic deficiencies in platelet adhesion receptors such as the GPIb complex (as in Bernard–Soulier syndrome) and the $\alpha_{IIb}\beta_3$ integrin (as in Glanzmann thrombasthenia) result in hemorrhagic symptoms similar to those in patients with thrombocytopenia (Table 15.6). Genetic deficiencies in the leukocyte β_2 integrins (as in leukocyte adhesion deficiency-1, LAD-1) are associated with frequent severe bacterial infections and a failure of neutrophils to enter the infected tissues. Similar symptoms are seen in patients with a congenital defect in fucose metabolism that prevents the synthesis of the carbohydrate ligands for selectins (LAD-2). A recently identified set of patients has both hemorrhagic symptoms and life-threatening infections (LAD-3). The molecular mechanism is attributable to mutations in an intracellular protein kindlin-3, which binds to β1, β2, and β3 integrin cytoplasmic tails upon platelet and leukocyte activation. These patients have normal levels of integrin surface expression (see Table 15.6).

DYSREGULATED EXPRESSION OF ADHESION MOLECULES

Inappropriate expression of adhesion molecules has been implicated in thrombotic and inflammatory disorders and in tumor metastasis. For example, erythrocytes from patients with sickle cell anemia adhere to each other, to leukocytes, and to the endothelium, contributing to vasoocclusive crises. These adhesive events may reflect, in part, the expression of integrins and selectin ligands not normally found on mature erythrocytes. Inappropriate adhesion and activation of platelets on exposed atherosclerotic plaques may contribute to thrombosis and acute ischemic coronary artery syndromes. Dysregulated expression of selectins on the endothelium of ischemic blood vessels during myocardial infarction or shock may contribute to neutrophil-mediated tissue necrosis after reperfusion of the vessel. Mediators released while the neutrophils are adherent in the reperfused vessels may activate integrin function, strengthening adhesion and generating further signals that release destructive oxygen radicals and proteases within the vasculature. Finally, malignant cells appear to use molecules normally used for the adhesion of blood cells to promote metastatic spread through interactions with platelets, endothelial cells, and extravascular matrix.

These examples underscore the importance of proper regulation of adhesion molecule expression in the physiology of blood cells and their interactions with the vascular endothelium.

CHAPTER 16

CURRENT BIOLOGY OF STEM CELL HOMING AND MOBILIZATION: DYNAMIC INTERACTIONS BETWEEN HEMATOPOIETIC STEM AND PROGENITOR CELLS AND THEIR SURROUNDING BONE MARROW MICROENVIRONMENT

Orit Kollet, Montaser Haddad, Priyasmita Chakrabarti, Alejandra Ordonez-Moreno, and Tsvee Lapidot

INTRODUCTION

Hallmarks of hematopoietic stem and progenitor cell (HSPC) function include their dynamic metabolism, active bi-directional migration (bone marrow [BM] homing, egress, recruitment, and mobilization to the blood), durable multilineage BM and blood repopulation potential, self-renewal and chemotherapy resistance. Hematopoietic stem cells (HSCs) mainly reside in the BM, and their chemotherapy resistance requires their quiescence, adhesion, and metabolic interactions with bone-forming stromal cells. However, HSPCs are also actively released daily to the circulation at low levels as part of steady-state homeostasis and blood replenishment. This minute egress is profoundly accelerated via metabolic elevations of reactive oxygen species (ROS) levels leading to enhanced HSPC development, mobilization, and recruitment to the circulation during stress-induced hematopoiesis (e.g., blood loss and infections) as part of host defense and repair mechanisms. BM reconstitution requiring HSPC migration in the opposite direction, from the circulation across the blood-BM endothelial barrier into the BM and their lodgment in their stromal niches, also requires metabolically active directional navigation, a process termed homing. The ability of intravenously transplanted HSPCs to actively home to the BM is the first and essential step for successful engraftment and durable repopulation, following clinical BM transplantation. In recent years, several key players and mechanisms controlling HSPC function and dynamic regulation of the BM microenvironment, including the central role of the nervous, immune, coagulation, purinergic, and complement systems, have been revealed. In functional preclinical experimental mice models, during steady-state daily-light onset induces transient elevations of BM norepinephrine (NE) and tumor necrosis factor (TNF), which further lead to a transient rise in BM HSPC ROS levels. These dynamic changes metabolically program BM HSPC proliferation, differentiation, migration, and egress to replenish the blood with new mature cells, including the active daily release of immature HSPCs. Darkness onset induces lower transient elevations of BM NE and TNF, leading to a lower burst of BM HSPC ROS levels. These transient elevations at night activate local BM production and secretion of the darkness hormone melatonin, which together with other factors metabolically reprogram BM HSPC self-renewal and retention accompanied by increased short and long-term repopulation potential.

Stress signals caused by bleeding, injury, as well as by viral and bacterial infections induce massive proliferation and differentiation of BM HSPCs, accompanied by accelerated progenitor and mature cell recruitment to the circulation as part of host defense and repair. This process is mimicked by clinical mobilization protocols, which transiently expand the circulating HSPC pool, allowing the efficient harvest of stem and progenitor cells for clinical BM transplantation. Importantly, clinical mobilization of patients for autologous transplantation is often associated with poor yields of circulating HSPC due to the advanced disease state, heavy toxicity of clinical pretreatments, and old patient age. Both HSPC homing and mobilization involve metabolically active multi-step interactions with the BM microenvironment, including the adhesion machinery, proteolytic enzymes, cytokines, and chemokines. A dominant mechanism involves the interactions between the key BM stromal chemokine CXCL12 (also termed SDF-1) and its major receptor CXCR4, functionally expressed also by HSPCs. These interactions regulate HSPC motility (both homing and mobilization), proliferation, adhesion, BM retention, quiescence, and chemotherapy resistance. In addition to CXCL12, BM stromal and endothelial cells also functionally express CXCR4, and many mobilizing agents induce BM CXCL12 secretion to the blood, creating a gradient leading to HSPC mobilization. For clinical requirements, HSPC mobilization is induced by a variety of agents. Among them are repeated stimulation with the myeloid cytokine granulocyte colony-stimulating factor (G-CSF), the CXCR4 antagonist AMD3100 (also termed Plerixafor), and DNA damaging chemotherapy drugs such as cyclophosphamide and total-body radiation, which all induce BM CXCL12 secretion. HSPC mobilization involves in addition to the CXCL12/CXCR4 axis among others, also the stem cell factor (SCF)/c-Kit axis, the pro-inflammatory factors NE, TNF, sphingosine 1 phosphate (S1P), hepatocyte growth factor (HGF), and their receptors, complement, thrombin, and proteinase activated receptor one (PAR1).

This chapter discusses recent findings concerning the biology of HSPC homing and release during steady-state and their mobilization and recruitment during stress-induced conditions. This chapter emphasizes major signals controlling HSPC homing, BM retention, chemotherapy resistance, and clinical mobilization with a major focus on the CXCL12/CXCR4 axis.

LESSONS FROM STEADY-STATE HOMEOSTATIC REGULATION OF HEMATOPOIETIC STEM AND PROGENITOR CELLS

Daily Light- and Darkness-Onset Induced Signals Maintain Blood Replenishment Together With Self-Renewal of Long-Term Repopulating Hematopoietic Stem Cells

BM retained HSPCs daily give rise to the entire yet diverse repertoire of mature blood and immune cells while maintaining the BM reservoir of undifferentiated progenitor cell pool including long-term repopulating stem cells (LT-HSCs) throughout adult life. How these contrasting tasks, requiring induction of proliferation, differentiation, and migration versus quiescence, self-renewal, and BM retention are regulated and controlled is not fully understood. Recent studies revealed that daily light and darkness onset and circadian rhythms metabolically regulate mouse HSPC migration and development as well as their BM retention and self-renewal. One hour post light onset a transient increase in the level of ROS within BM retained HSPCs was observed. This increase is driven by and requires a transient increase in BM NE and TNF levels, induced by the onset of light. These modulations in the surrounding BM microenvironment including reduced levels of CXCL12 and higher surface expression of CXCR4 by HSPCs metabolically regulate HSPC differentiation and migration, accompanied by increased permeability of BM-blood vessels. Consequently, immature and maturing leukocytes are released from the BM to the blood, peaking five hours post light initiation, to replenish the blood. In contrast, one hour following the onset of darkness, similar triggering processes are observed, although weaker signals are generated: lower transient increases in ROS levels within BM retained HSPCs are following lower increases in BM NE and TNF. These darkness-onset mediated transient increases, metabolically inducing local synthesis and secretion of the dark hormone melatonin in the mouse BM. Melatonin together with other cytokines such as PGE2, directly and indirectly, promotes retention of HSPCs in the BM. Directly, ROS levels within HSPCs and primitive LT-HSCs are further reduced following melatonin and PGE2 stimulation. Indirectly, melatonin and PGE2 also reduce the permeability of mouse BM endothelial vessels via nocturnal S1P augmentation-mediated COX2 elevation. Acting together, retention of BM HSPCs is upregulated, and these primitive cells, when harvested for transplantation at darkness during the night, are endowed now with higher homing and LT-HSC repopulation potential. Taken together, these results reveal how light onset metabolically regulates HSPC differentiation and migration to replenish the blood with new mature blood and immune cells with a finite life span. Furthermore, the onset of darkness metabolically reprograms HSPCs, facilitating their BM retention, maintenance, and self-renewal via daily BM melatonin and PGE2 bursts.[1,2]

Mechanisms of Long-term Repopulating Stem Cell Chemotherapy Resistance via Anchorage to Their Supportive Bone Marrow Niches: The Dual Roles of the Coagulation-Related, Proteinase-Activated Receptor One Axis

The major coagulation receptor, PAR1, is well known in the context of coagulation and inflammation. PAR1 has two different signaling cascades leading to opposite outcomes. One cascade leading to pro-inflammatory and pro-coagulant activity is induced by thrombin-mediated PAR1 signaling. The other cascade, leading to anti-inflammatory and anti-coagulation, is initiated by interactions of activated protein C (aPC) with endothelial protein C receptor (EPCR) and PAR1. Recent studies reported that PAR1 is functionally expressed not only in the blood involving coagulation processes but also within the BM, a site with no coagulation. Hence, PAR1 is expressed by BM stromal, endothelial, and hematopoietic cells. EPCR as well is functionally expressed by BM endothelial cells and also by some other hematopoietic cells, including the most primitive human and mouse LT-HSCs that are endowed with the highest multilineage long-term repopulating potential in transplanted mice. Recent results revealed that PAR1 signaling in HSPCs determines their location, either targeting their retention in the BM (including LT-HSCs) or their egress and mobilization, independently of coagulation. In mice, thrombin-induced PAR1 mediated secretion of CXCL12 by BM stromal cells and increased the permeability of BM endothelial vessels. In parallel, thrombin/PAR1 signaling elevated generation of the signaling free radical nitric oxide (NO) in HSPCs, including in primitive EPCR$^+$ LT-HSCs. Other effects promoted by the NO elevation in HSPCs were: shedding of EPCR, increased expression of surface PAR1 and CXCR4, higher activity of the cell-cycle and motility regulator Cdc42, enhanced CXCL12/CXCR4-directed migration, which altogether led to rapid HSPC mobilization. Interestingly, despite the shedding of EPCR, primitive LT-HSCs still contain intracellular storage of EPCR that, upon their transplantation and homing to the BM, is re-expressed on the surface and is required for long-term BM repopulation. In contrast, aPC/EPCR/PAR1 signaling in primitive BM retained EPCR$^+$ LT-HSCs exert the opposite effects, namely, inhibition of NO generation, reduction of Cdc42 activity, and increase of VLA4-mediated adhesion, which all together boost BM retention. The dual activity of PAR1 is clinically relevant. Activation of this pathway in mouse BM retained EPCR$^+$ LT-HSCs is essential for acquiring chemotherapy resistance. Furthermore, the manipulation of NO levels can be applied to increase HSPC homing[3] or mobilization as well as for increasing their BM retention and chemotherapy resistance.[4,5]

Finally, expression levels of PAR1 by circulating human HSPCs and mature leukocytes is highly important for the outcome of clinical stem cell transplantation. PAR1 signaling is essential for CXCR4 mediated directional migration of both human and mouse HSPCs toward a gradient of CXCL12 in vitro. Importantly, in clinical settings, the levels of PAR1 expression by mature mononuclear cells in the blood of healthy donors during steady-state correlate with their CXCR4-dependent in vitro migration toward CXCL12. Moreover, upon G-CSF treatment in these healthy donors, the yield of their mobilized CD34$^+$ HSPCs also correlated with the levels of PAR1 expression by circulating HSPC and mature leukocytes before treatment. Furthermore, higher PAR1 basal expression correlated with faster kinetics of hematological recovery in allogeneic matched transplanted patients.[6]

Hematopoietic Stem and Progenitor Cell Regulation via Dynamic Interactions With the Blood-BM Endothelial Barrier and the Stromal Microenvironment

Mature red blood cells and platelets are present in the blood but are absent from the BM due to the selective blood-BM endothelial barrier. This selective endothelial barrier dynamically regulates the trafficking of HSPCs and mature leukocyte to and from the BM. Defining the architecture of the blood-BM barrier reveals different types of blood vessels with distinct roles, including the more permeable sinusoids, which are connected to the less-permeable capillaries. These, in turn, are continued by small arterioles. Trafficking of all leukocytes, including HSPCs, to and from the BM (homing and mobilization, respectively) occurs exclusively via the more permeable sinusoids. These vessels are associated with higher S1P and ROS levels, transferred from circulating red blood cells and platelets, conditions that induce HSPC migration and differentiation. In contrast, the less-permeable capillaries and arterioles provide low-ROS containing BM microenvironments also by physically shielding ROS entry from the circulation. As a result, low-ROS levels adjacent to the BM endosteal region provide niches for undifferentiated stem cells.[7] Importantly, total-body irradiation or chemotherapy that are applied as recipient preconditioning for BM transplantation transiently destroy the blood-BM endothelial barrier, allowing mature red blood cells and platelets to penetrate the BM. However, immature endothelial stem cells in the mouse BM vasculature can regenerate, and lead to the formation of new blood vessels and restoration of the barrier traits. The integrity of the BM-blood barrier is also deteriorating during aging. In old mice, the barrier becomes more permeable, allowing increased ROS levels to penetrate the BM, leading to conditions of chronic inflammation, which are associated with anemia, reduced host immunity, and osteoporosis. This inflammatory state can be attenuated and even reversed in old mice by activation of BM endothelial stem cells.[5]

The toxic effect of high ROS levels and the need to balance its levels in BM HSPCs is controlled by niche cells. An example is the BM non-myelinated Schwann cells, which are also ROS sensitive. These cells that are located in the low-ROS harboring BM endosteal region near less-permeable blood vessels provide a niche for

HSPCs via TGF secretion. Similarly, BM HSPCs are located adjacent to PGE2 secreting niche COX-2^+ monocyte/macrophages and megakaryocytes closed to sinusoids that both maintain their ROS^{low} state.[5,8] Another rescuing mechanism during chemotherapy-induced DNA damage is the ability of HSPCs to transfer their accumulating excess ROS levels to the attached BM niche stromal cells in order to prevent their apoptosis, which leads to lethal infection and hematology failure.[9] Preliminary results suggest that this excess ROS-transfer is a result of mitochondria transfer between LT-HSCs and their niche supporting BM stromal cells.[10] BM retaining HSPCs localize and anchor to their stromal niches via adhesion interactions that provide them with signals maintaining their quiescent, undifferentiated, non-motile, and low metabolic states. Different cell types, mainly stromal but also others, have been suggested as "HSC niche cells." Thus, mesenchymal stromal progenitor cells, including CXCL12- and SCF-expressing CAR, Nestin and leptin-receptor expressing stem cells, endothelial cells, non-myelinated Schwann cells, monocyte/macrophages, megakaryocytes, nerve fibers, and adipocytes have all been reported to regulate HSPCs and their function. The most primitive BM stromal cells of the niche have a common feature of high CXCL12 expression that is required for maintaining LT-HSC quiescence, BM retention, and chemotherapy resistance.[11–13] BM stromal niche-cells express CXCR4 as well. Functionally, CXCL12/CXCR4 signaling in these cells promotes niche regeneration after irradiation and recovery of hematopoiesis after transplantation.[14] Adult HSPC niches are also located within bone cavities and are essential for stem cell quiescence and chemotherapy resistance. Bone cavities are generated and regulated by signals originated by bone-forming osteoblasts and bone-resorbing osteoclasts. Studies in mice show that processes of bone formation are crucial for the development of BM hematopoiesis, while osteoclast activity facilitates both bone degradation and HSPC mobilization.[15–17] A recent study reported that active cycling and expanding primitive LT-HSCs are located in BM cavities with neighboring bone-remodeling activity,[18] emphasizing the major role of this region in HSC regulation. However, total-body irradiation disrupts the balance necessitating signals for restoration of new bone formation and controlled hematopoiesis. Interestingly, massive recovery of host osteoblasts following lethal body irradiation is mediated by host megakaryocytes that are recruited to the endosteal region in order to facilitate osteoblast proliferation and concurrently inhibit osteoclast activity.[19] These studies demonstrate the profound regulatory impact that bone-remodeling processes have on HSPC function and moreover suggest that a durable turnover of HSPC BM niches is required for the ongoing maintenance of the niche supportive function.

MEDICAL APPROACHES ORIGINATING FROM UNDERSTANDING MECHANISMS THAT REGULATE PHYSIOLOGICAL HSPC TRAFFICKING, FOR THE SAKE OF CURATIVE STEM CELL TRANSPLANTATION PROTOCOLS

Establishment of Functional Preclinical Immune-Deficient Mice Models to Study Human Hematopoietic Stem Cell Trafficking and the Major Role of the CXCL12/CXCR4 Axis

Mouse stem cell homing is mostly investigated in experimental BM transplantation assays. Recipient mice are preconditioned with total-body irradiation, followed by competitive transplantation of host BM cells with genetically matching donor HSPCs to prevent their rejection, but are genetically marked to track their donor cell engraftment. To identify and characterize human HSPCs and their repopulation potential in vivo, functional preclinical small animal models using immune-deficient NOD/SCID mice as recipients were developed based on conventional BM transplantation protocols. The NOD/SCID model, which is currently the gold standard for human HSC research allowed the identification of primitive human SCID-repopulating stem cells (SRC) and their hierarchy. This model was also utilized to understand the complex mechanisms regulating BM homing, engraftment, and mobilization of human HSPCs.[20] Human and murine CXCL12, the major stem cell chemokine, are cross-reactive and differ in only one amino acid, enabling homing and engraftment of human HSPCs, which functionally express its major receptor CXCR4, in transplanted immune-deficient mice. Homing and engraftment of immature human $CD34^+$ stem cells to the recipient BM requires host preconditioning with sublethal total-body irradiation or chemotherapy. These myeloablative regimens have been shown to disrupt the physical blood-BM endothelium barrier, induce a dramatic elevation of CXCL12 production and secretion by BM stromal cells, and create a chemotactic gradient toward the BM, which all facilitate the attraction of human transplanted $CD34^+CXCR4^+$ cells including the primitive $CD34^+CD38^+CXCR4^+$ stem cells to the BM. The CXCR4/CXCL12 axis is essential both for human stem cell homing and for their mobilization in transplanted NOD/SCID chimeric mice, as detailed in the homing and mobilization sections. Functional, preclinical immune-deficient murine models, which tolerate human HSPC xenografts, are important for the identification and characterization of human stem cells, for better understanding of the mechanisms involved and the molecules participating in the biological regulation of HSPC trafficking to and from the BM. The high homology of mechanisms regulating HSPC function shared between these preclinical functional BM transplantation models and transplanted human patients emphasize the clinical relevance and potential of these experimental models.

HEMATOPOIETIC STEM AND PROGENITOR CELL HOMING

Migration of HSPCs from the circulation and their extravasation across the physical barrier of the blood vessels into the BM require active steering, a process termed homing. Physiological homing occurs during development, when HSCs relocate from the fetal liver, the pre-natal hematopoiesis site, to the BM, the site of childhood, and adult hematopoiesis. Clinical stem cell transplantation mimics this process where HSPCs are infused into the blood of ablated recipients home to their BM as a critical and essential first step for successful engraftment of the BM, the predominant physiologic site of hematopoiesis. The BM endothelium is the first anchoring site for homing stem cells, exposing them to presented adhesion molecules (e.g., very late antigen 4 [VLA-4]/vascular cell adhesion molecule 1 [VCAM-1], and CD44/hyaluronic acid [HA] interactions) and stimulating chemokines (CXCL12/CXCR4 signaling). BM sinusoidal blood vessels, through which trans-endothelial migration takes place in mice[7] and likely in humans as well, are composed of specialized cell structures that regulate cell trafficking. The homing process is initiated by a CXCL12/CXCR4-mediated guiding signal, leading to firm adhesion and docking to the vascular sinusoidal wall, which induces cytoskeleton rearrangement and activation of integrins (e.g., VLA-4), and metalloproteinases (e.g., MMP2/9). These cellular alterations are followed by trans-migration across the physical BM-blood endothelial and extracellular matrix barriers.[20]

The Essential Role of the CXCL12/CXCR4 AXIS in the Regulation of Hematopoietic Stem and Progenitor Cell Homing

CXCL12/CXCR4 interactions and downstream signaling have been implicated in retention, migration, homing, and mobilization of HSPCs during steady-state homeostasis as well as during injury.[20] Both human and murine BM mesenchymal stromal cells, endothelial cells, and endosteal bone-lining osteoblasts, express and secrete high levels of CXCL12, observed in regions highly populated with HSPCs. Expression of CXCR4 is dynamically regulated by the levels of its ligand CXCL12, where a high concentration of soluble CXCL12 leads to CXCR4 internalization and reduced surface expression. Consequently, the expression of CXCR4 on transplanted circulating HSPCs is very dynamic and allows their direct chemo-attraction toward a high level of CXCL12 found in the BM, facilitating the homing process. A correlation observed between the migration potential of patients' CD34$^+$ HSPCs to a CXCL12 gradient in vitro, and hematopoietic recovery after autologous transplantation[21] demonstrates the clinical essential role of this axis in stem cell transplantation treatments. Importantly, in healthy donors (similar to PAR1 levels of expression[6]), the levels of surface CXCR4 expression by CD34$^+$ HSPCs correlated with their G-CSF-induced mobilization, CXCL12-induced migration in vitro, and hematopoietic recovery in matched transplanted patients.[21] Therefore, manipulations of this navigation machinery can facilitate or inhibit HSPC homing. For instance, CXCR4 expression by HSPCs can be upregulated ex-vivo, as a pretreatment aiming to accelerate their homing efficiency. Thus, genetic intervention by ex-vivo overexpression of CXCR4 enhanced the homing capacity of transplanted human HSPCs. CXCR4 expression can be also imposed by ex-vivo cytokine stimulation. A major cytokine in this context is stem cell factor (SCF, also termed c-Kit ligand). SCF is expressed by various BM stromal niche cells that co-express CXCL12 as part of the niche supporting traits. SCF regulates HSPC homing and plays an important role in hematopoiesis. Prestimulation of human or murine HSPCs with SCF increased their surface CXCR4 expression and in vivo homing through increased migration rates and adhesion via the VLA-4 and VLA-5 integrins. This superior homing capacity demonstrates the crucial role of adhesion interactions for proper rolling on the BM endothelium, which is essential for homing and retention of HSPCs in their stromal supportive niches. Similarly, the cytokine HGF as well, increased CXCR4 expression by human HSPCs and in line, their migration toward CXCL12. Raising the levels of cellular NO in HSPCs by exposure to NO donors achieves a similar effect, increasing CXCR4 expression and consequently, the homing and engraftment potential of human cord blood, BM or G-CSF-mobilized HSPCs as well as mouse HSPCs.[3,22] In contrast, the administration of neutralizing anti-CXCR4 antibodies impaired the homing of immature human CD34$^+$ HSPCs to the BM of transplanted immune-deficient mice.[20] Given the important clinical challenge of improving HSPC engraftment and BM repopulation, upregulation of CXCR4 expression prior to stem cell transplantation is a promising approach.

The dynamic expression of CXCL12 is also a key regulator of the HSPC function. The most prominent example is the rise of BM CXCL12 following total-body irradiation or chemotherapy treatment as demonstrated in mice, applied for host preconditioning. Once this rise is inhibited by injection of anti-CXCL12 neutralizing antibodies to the preconditioned immune-deficient mice, human HSPC homing and engraftment were abrogated. Administration of high doses of CXCL12 supports survival and quiescence of BM retaining HSPCs, while low doses promote the upregulation of CXCR4, proliferation, and migration. Accordingly, in vivo pretreatment with a high dose of CXCL12 locally increased the homing of human repopulating cells. Interestingly, physiologic mechanisms act to balance CXCL12 availability. Concentrations of this chemokine in the BM or plasma can reciprocally interchange and direct HSPC navigation. The noncleaved and active form of CXCL12 can transfer from the blood into the BM crossing the endothelial barrier in a CXCR4-dependent manner. This increase in concentrations of BM CXCL12 functionally enhances the homing capacity of human CD34$^+$ progenitors transplanted in NOD/SCID mice.[20] Inline, depletion of CXCL12-expressing stromal niche cells results in defective hematopoiesis and reduced homing of transplanted mouse HSPCs to the BM, demonstrating the crucial role for CXCL12 in homing of HSPCs.[12]

Taken together, enhancing CXCR4 expression on HSPCs and inhibiting CXCL12 degradation or raising its levels in the BM are promising approaches for creating a stable chemotactic response in order to direct HSPC homing into the BM.

HEMATOPOIETIC STEM AND PROGENITOR CELL MOBILIZATION: A DYNAMIC MULTI-FACET PROCESS

HSPCs, actively retained in the BM anchored to their stromal microenvironment, proliferate and differentiate to all mature leukocytes and erythrocytes to replenish blood and immune cells. In addition to mature and maturing leukocytes, low levels of HSPCs are also daily released to the blood as part of steady-state homeostasis. The timing of this daily HSPC egress is driven by light-induced signals derived from the nervous system.[1,2]

Hematologic stress situations such as bacterial-induced inflammation (mimicked by LPS or endotoxin), bleeding, and administration of cytotoxic agents such as radiation and chemotherapy all exert demands for accelerated hematopoiesis. Consequently, steady-state rates of HSPC egress are dramatically augmented leading to HSPC recruitment as part of host defense and repair mechanisms. This recruitment of human and mouse HSPCs from the BM to the blood is also achieved by clinical protocols, such as repeated G-CSF stimulations, which are used to expand and to mobilize the HSPC pool in order and to more easily harvest them from the blood for clinical BM transplantation. Stress-induced HSPC mobilization is a complex multi-step process involving activation of motility mechanisms; signals of various cytokines; and changes in chemotactic signals (e.g., CXCL12 and CXCR4), proteolytic enzymes, and other extrinsic factors that enable detachment of HSPCs from their BM niches. Some mobilizers such as repeated stimulations with the cytokine G-CSF first induce HSPC proliferation and differentiation while others rapidly acting are merely metabolically activating the mobilization machinery. Induction of mobilization settings modulates also the permeability of the BM-blood endothelial barrier and the anchoring-facilitating signals of BM HSPC niches.

The CXCL12/CXCR4 Axis as a Driving Force Leading to Hematopoietic Stem and Progenitor Cell Mobilization

The CXCL12/CXCR4 axis has important roles in HSPC homing to the BM, retention, quiescence, and chemotherapy resistance. Impairment of CXCL12 or CXCR4 expression levels in murine embryos results in multiple lethal defects, including lack of stem cell seeding of the BM. In order to circumvent lethality, conditional knock-out models were established. Induced-deletion of CXCR4 in the hematopoietic system of the adult mouse or ablation of CXCL12 in the BM stroma both led to severely reduced BM cellularity and HSC numbers as well as impaired competitive repopulation capacity. Conditional deletion of CXCR4 or CXCL12 also results in dramatically increased HSPC numbers in the peripheral blood and spleen since the cells were continuously cycling, losing their chemotherapy resistance[13] and revealing that the lack of CXCR4 hampers their retention in the BM. Selective chemical antagonists of CXCR4, such as AMD3100, were originally developed to block CXCR4 mediated HIV infection but failed to do so in vivo. Nevertheless, serendipitous research revealed that upon AMD3100 administration, mouse, primate, and human HSPCs undergo rapid mobilization within hours and the mobilized HSPCs retain a high in vivo repopulation potential. Mechanistically, AMD3100 enhanced secretion of CXCL12 from BM stromal cells and its release to the circulation, leading to the rapid CXCR4-dependent mobilization of HSPCs.[23] AMD3100 is the only chemokine receptor antagonist utilized clinically for inducing mobilization, either alone or in combination with G-CSF since it synergistically augments G-CSF-induced mobilization. The different kinetics and mode of action make AMD3100 an effective mobilizing agent in murine models, and human patients were found to poorly mobilize in response to G-CSF only.[23]

The essential role of CXCL12/CXCR4 signaling in HSPC retention can be inferred from the observations that following G-CSF administration, CXCL12 levels in the BM are transiently increased followed by its downregulation at both protein and mRNA levels, enabling transient and local CXCL12 gradients toward the blood. These modulations in the ligand levels following G-CSF treatment are associated with CXCR4 upregulation on immature murine BM HSPCs as well as on immature human $CD34^+$ HSPCs and the more primitive $CD34^+CD38^-$ stem cells resident in the BM of G-CSF-treated chimeric mice. Blocking either CXCR4 or CXCL12 blocks both G-CSF- and AMD3100-induced mobilization, demonstrating the key role of the CXCL12/CXCR4 axis in murine HSPC mobilization.[23]

Secreted CXCL12, as well as AMD3100, can activate the metalloprotease MMP-9, which in turn cleaves and degrades this chemokine, and induced the release of membrane-bound SCF, participating in the enhanced migration capacity and mobilization of HSPCs to the periphery.[23] Inline, repetitive daily administrations of CXCL12 for five consecutive days facilitated murine HSPC mobilization.[15] In summary, impeding CXCL12/CXCR4 signaling in the BM results in loss of retention since active membrane-bound CXCL12/CXCR4 signaling is required for stem cell adhesion, quiescence, and chemotherapy resistance in the BM.

Dynamics of the Hematopoietic Stem and Progenitor Cell Niches and the Bone Marrow Microenvironment During Mobilization

The two major roles of the BM microenvironment are to regulate hematopoiesis and mature blood cell production, together with providing quiescent, primitive BM retained LT-HSCs with chemotherapy resistance, in order to prevent lethal hematology failure and infections. Coupling of bone degradation by HSPC-derived and monocyte-derived osteoclasts and new bone formation carried out by mesenchymal stem cell (MSC)-derived osteoblasts, is part of a complex network implementing the process of bone remodeling. Noteworthy, osteoblasts and osteoclasts maintain bone equilibrium by acting also on the endosteum region in the vicinity of HSPCs. These regions are highly vascularized. Moreover, both osteoblasts and osteoclasts attached to the endosteal bone of mouse calvaria are observed close to BM sinusoidal capillaries.[24] Osteoclast activity has been shown to also mediate HSPC mobilization[15] but is also crucial for the normal function of BM HSPC niches,[25] demonstrating the major role these cells play in HSPC regulation. Thus, the endosteal neighboring HSPC niches are dynamically altered during bone remodeling, affecting HSPC function and maintenance during a steady state. Once mobilization is induced by clinical procedures the BM microenvironment experiences dynamic changes. G-CSF or cyclophosphamide injections, as part of clinically-oriented HSPC mobilization protocols, lead to the disappearance or altered morphology of mature bone-lining osteoblasts, resulting in their reduced function, which is also associated with reduced transcription of CXCL12. Of interest, upon G-CSF administration, osteoblasts rapidly expand, prior to their apoptosis, promoting HSPC proliferation, which in turn enables the loss of HSPC retention. The importance of BM stromal cells for the retention of HSPCs can be illustrated, for example, by the conditional deletion of the cell-cycle regulator Retinoblastoma protein (Rb). Not only the absence of Rb in the murine hematopoietic system but also the absence of Rb in the BM stroma alone is sufficient to increase the numbers of circulating HSPCs, in addition to a myeloproliferative-like disease and extramedullary hematopoiesis. Other BM cell types are also affected by the pro-inflammatory mobilization process, and in turn, exert signals influencing HSPCs. This list contains activated neutrophils and osteoclasts, which secrete proteolytic enzymes mediating the degradation of the extracellular matrix, CXCL12, and SCF.[15,23] Inline, depletion of osteal macrophages termed osteomacs lead to HSPC mobilization due to a reduction in BM CXCL12 and SCF.[26] BM endothelial vessels are also modulated during mobilization. Particularly, AMD3100 reduces expression of CXCL12 and SCF, particularly on BM sinusoids, and increases vascular permeability involving CXCR4 signaling.[5,7] Complement activity and purinergic signaling have also been shown to regulate HSPC egress and mobilization.[27] Taken together, HSPC mobilization is an active process that involves changes in metabolic activity, structural arrangement, and availability of BM HSC niche signaling components, all disrupting the adhesion and anchorage of HSPCs in their protecting niches.

CLINICAL RELEVANCE AND FUTURE DIRECTIONS

BM transplantation procedures, which are routinely used to treat patients with hematological malignancies, as well as inherited genetic disorders, require the collection of mobilized HSPCs from the donor's circulation. Therefore, the characterization of new agents for improved stem cell mobilization protocols has become a major focus in recent decades. The HSPC mobilization process is not credited only to key motility mechanisms, but also to microenvironmental dynamics. Clinical BM transplantation applying current mobilization protocols includes repeated G-CSF regimens and chemo-mobilization achieved by chemotherapy treatment combined with G-CSF. Despite the wide range of therapeutic strategies used, most of them have either failed to show a clear advantage to standard mobilization regimens or were associated with substantial adverse effects (e.g., chemo-mobilization). For the introduction of CXCR4 antagonists, e.g., AMD3100, there is a renewed optimization in the management of difficult to mobilize patients. AMD3100 mediates the rapid secretion of CXCL12 from BM stromal cells and its release to the circulation and increased BM endothelial cell permeability[7] result in stem and progenitor cell mobilization. Treatment with AMD3100 exhibits marked synergism with G-CSF, suggesting their distinct and complementary mechanisms of action to induce HSPC mobilization. Several studies have shown success in mobilization capacity of previously poor-mobilizing myeloma, non-Hodgkin lymphoma, and Hodgkin lymphoma patients.

As to HSPC homing, the paradox of preconditioning, having a “double-edged sword” effect, is the following: on one hand, killing dividing defective/malignant immune and blood progenitor cells and evacuating the BM niches for lodgment of donor transplanted BM HSPCs; on the other hand, generating stress conditions turn the HSPC migration machinery, the profile of niche signals, and BM barrier permeability into mobilization-favoring status, which sums up in lower homing efficiency. A solution for this complication is suggested by transplantation of a large amount of HSPCs without host preconditioning, leading to high durable donor stem cell engraftment levels.[28] The use of cord blood is limited at present to pediatric patients and adults of low body weight because of the low number of $CD34^+$ progenitors contained in each cord blood unit. For this reason, the major disadvantage of cord blood transplantation in adult patients is, delayed engraftment and the T cells in the cord blood are naïve and in low numbers. Attempts to overcome this problem consisted of double cord blood transplants or combined transplantation of mobilized or BM-derived $CD34^+$ cell infusion from a matched donor, achieving transient engraftment until the cord blood cells reconstitute the BM. A recent publication shares a protocol to expand mouse BM LT-HSCs in a 28-day-long in vitro culture derived from 50 sorted HSCs. These conditions afford between 236- and 899-fold expansions of functional HSCs that upon transplantation highly repopulated non-preconditioned host mice.[29] Finally, promising strategies are aiming at increasing CXCR4 expression prior to HSPC transplantation by in vitro exposure to NO donors, as shown for human and mouse HSPCs.[3,22,30] Interestingly, the HSC self-renewal agonist UM171 balances pro- and anti-inflammatory signals, with exclusive induction and expansion of human LT- HSCs. In vitro expansion of human CB $CD34^+$ HSCs with UM171 led to the appearance of a small population of $EPCR^+CD34^+$ HSCs. Notably, only $EPCR^+$ (but not $EPCR^-$) human CB HSCs were endowed with robust high-level multilineage repopulation and serial reconstitution capacity in transplanted immunodeficient NOD/SCID mice. Importantly, EPCR function protected human LT-HSCs from TNF and UM171 mediated hyper-inflammatory responses by preventing NO overproduction in primitive $EPCR^+$ LT-HSCs, potentially leading to cell-death and compromised HSC function.[30] These results are in agreement with chemotherapy resistance of mouse BM retained $EPCR^+$ LT-HSCs, which is induced via aPC/EPCR/PAR1-mediated NO inhibition, leading to reduced Cdc42-GTP activity and increased VLA-4 mediated stem cell adhesion and BM retention.[4]

Figure 16.1 MECHANISMS MEDIATING HOMING, RETENTION, AND MOBILIZATION OF BONE MARROW HEMATOPOIETIC STEM AND PROGENITOR CELLS. **Homing:** HSPC transplanted by intravenous infusion, home to the bone marrow crossing the sinusoidal barrier following CXCL12 gradients. Homing HSPCs express high levels of surface CXCR4 and PAR1 (required for CXCL12-induced migration), are motile, and are active metabolically, containing high levels of NO and ROS. **Retention:** BM retained LT-HSCs are attached via adhesion interactions to niche stromal cells expressing surface CXCL12 and SCF. These primitive and quiescent cells are endowed with high repopulation potential and are chemotherapy-resistant due to their adhesion and metabolic interactions with stromal niche cells. BM retained LT-HSCs express low levels of surface CXCR4 and c-Kit, together with high levels of EPCR, and demonstrate low metabolic activity manifested in low contents of NO and ROS. **Mobilization:** Stress-induced mobilization involves an increase in thrombin activity leading to EPCR-shedding, upregulation of CXCR4 and PAR1, high metabolic activity indicated by high NO and ROS content, and HSPC proliferation and differentiation and activation of the migration machinery, which together with the release of CXCL12 from BM stromal niche cells to the circulation lead to HSPC mobilization. *BM*, Bone marrow; *EPCR*, endothelial protein C receptor; *HSPC*, hematopoietic stem and progenitor cell; *LT-HSC*, long-term repopulating stem cell; *MSC*, mesenchymal stem cell; *NO*, nitric oxide; *PAR1*, proteinase activated receptor one; *ROS*, reactive oxygen species; *SCF*, stem cell factor

CONCLUDING REMARKS

Cell-intrinsic processes in BM HSPCs and BM microenvironmental extracellular signals join to control HSPC modulating programs either to maintain quiescence, self-renewal, long-term repopulation capacity, and chemotherapy resistance while retaining them in their BM niches or to cycle, proliferate, differentiate and activate their migration machinery in order to egress from the BM and replenish the blood. The steady-state dynamics, balancing these bi-directional processes, led by light/darkness circadian signals, are further accelerated upon stress conditions favoring HSPC expansion and mobilization. These processes require metabolic alterations in HSPCs involving their cytoskeletal adjustment to the state of navigation, diminishing or reducing niche-retaining signals, turning the chemotactic gradient toward the blood, and increasing permeability of the selective BM-blood endothelial barrier. In order to facilitate stem cell homing, as desired during BM transplantation, migration machinery in HSPCs needs to be better activated when they are infused to the blood. However, efficient homing and engraftment will also be achieved if the BM microenvironment is preconditioned to increase vascular permeability and turn-over of the chemotactic gradient toward the BM. Once homed, HSPCs require retention-facilitating signals in order to lodge in their niches and durably regenerate hematopoiesis.

Multiple studies have been engaged with defining the entity, features, and composite of the HSPC niches. The activity of the CXCL12/CXCR4 pathway has a prominent role in HSPC homing, mobilization, retention, self-renewal, quiescence, adhesion, and chemotherapy resistance. The high expression of CXCL12 by endosteal osteoblasts, endothelial cells, and stem cell-supporting MSCs, implies the pivotal role of the niche dynamic regulation in HSPC function. This chapter discusses previously discovered as well as recent updates of mechanisms and pathways involved in the regulation of HSPC homing, egress and mobilization, emphasizing the major roles of the CXCL12/CXCR4 axis in the regulation of these complex interactive processes (key players are illustrated in Fig. 16.1).

CHAPTER 17

CONTROL OF CELL DIVISION

Martin Fischer and James A. DeCaprio

THE CELL DIVISION CYCLE

The mammalian cell cycle is divided into four phases: mitosis (M), deoxyribonucleic acid (DNA) synthesis (S), and the gap phases G1 and G2 (Fig. 17.1). Mitosis is recognized when cells visibly undergo cell division and chromatin becomes condensed, sequentially progressing through prophase, metaphase, anaphase, and telophase. The G1 phase occurs immediately after mitosis has been completed and ends when DNA synthesis begins. During the S phase, cells duplicate their entire genome by DNA replication. G2 occurs after DNA synthesis has been completed and before chromosomal condensation in mitosis. Although the duration of the S, G2, and M phases is relatively constant for most mammalian cells, there can be a large degree of variability in the duration of G1. Among the earliest observations regarding the generation time for cells, it was shown that by varying the growth conditions, the length of a cell division cycle could change, with the length of G1 responsible for most of this variability. Although cells progress through S, G2, and M phases in relatively invariable time periods, the length of the G1 phase is highly variable, and this variability is dependent at least in part on the presence of growth factors.

Quiescence and Differentiation

Quiescence (G0) is a non-proliferative state in which viable cells have left the cell cycle and may remain for prolonged periods. Quiescent cells may be difficult to distinguish morphologically from cells in a prolonged G1 phase, but they can be distinguished by different markers. Terminally differentiated cells, such as neutrophilic granulocytes, muscle cells, and neurons, have irreversibly exited the cell cycle during the process of differentiation and are examples of cells that have irreversibly entered G0. Other cells, including stem cells, reversibly enter G0 and may be induced to re-enter the cell cycle with appropriate stimuli, such as growth factors. Differentiation provides the organism with a supply of cells to execute specific and specialized functions. In some cell types, such as muscle and nerve cells, differentiation and proliferation are mutually exclusive fates, and cells undergo "terminal differentiation." In other cell types, such as those of the hematopoietic lineage, proliferation may continue after cells acquire differentiated characteristics. For example, erythroblasts, myeloblasts, and megakaryoblasts are committed to particular differentiation pathways and possess lineage-specific markers yet continue to proliferate. T and B lymphocytes are fully differentiated and express antigen-specific receptors but can be induced to proliferate when appropriately stimulated.

G1 Phase

G1, which occupies the period or gap between M and S phases, is the interval between the completion of one round of cell division and initiation of the next. Its duration is the most variable, can be prolonged depending on the cell type, and is subject to regulation by environmental factors such as the availability of growth factors and nutrients. It is the period of cell growth, and as a first approximation, the amount of time a cell spends in G1 is inversely related to its rate of proliferation. A certain increase in mass usually is required before the cell initiates the next S phase. When conditions are unsuitable for proliferation (e.g., because of insufficient nutrients or absence of mitogens), cells arrest in G1, and those that are already in S, G2, or M phase usually complete the round to which they have been committed and arrest only when they reach G1 again. For example, when the 40 S ribosomal protein S6 is missing, cells stop proliferation. If cell size or mass were not regulated, S phase entry might cause cells to become progressively smaller or be at risk for DNA replication errors because of insufficient substrates. Cell size regulation is intimately linked to ribosome biogenesis and nutrient-sensing systems, central to which are the phosphoinositide 3-kinase (PI3K) and target of rapamycin (TOR) pathways. Notably, when the MYC transcription factor is missing, cells slow their growth and often do not enter the S phase. Myelocytomatosis (MYC) transcription factor regulates *cyclin* and *cyclin-dependent kinase (CDK)* genes as well as genes involved in ribosome biogenesis and translation.[1] In aggregate, studies of a variety of cell systems indicate that cell size regulation is linked to cell proliferation, except in specialized cells that undergo endoreplication or in embryos shortly after fertilization, when G1 is virtually undetectable, and there is no cell enlargement. In the latter, the original mass of egg cytoplasm is partitioned among thousands of cells within a few hours without a noticeable increase in size.

S Phase

S phase is the period of wholesale DNA synthesis during which the cell replicates its genetic content; a normal diploid somatic cell with a 2 N complement of DNA at the beginning of the S phase acquires a 4 N complement of DNA at its end. (Recall that $N = 1$ copy of each chromosome per cell [haploid]; $2N = 2$ copies [diploid].) The duration of the S phase may vary from only a few minutes in rapidly dividing, early embryo cells to a few hours in most somatic cells. Early embryo cells generally "live off" the accumulated stores of maternal ribonucleic acid (RNA) and proteins present in the egg and are transcriptionally silent, whereas cells in later development and mature organisms must actively transcribe subsets of their genes to survive and maintain specialized functions. The longer time required for the latter to complete the S phase probably allows these cells to coordinate DNA replication with transcription and to preserve higher-order gene and chromatin structural information that influences gene expression for transmission to progeny cells.

G2 Phase

G2 is the period or gap between S and M phases when cells have finished replicating their DNA, are preparing to divide, and have a 4 N DNA content. For most cells entering the S phase, passage through G2 is "automatic," and the duration of G2 is fixed, except under unusual circumstances. For example, G2 duration can be extremely short and is essentially undetectable in rapidly proliferating, early embryonic cells.

M Phase

Mitosis, or M phase, is the period of actual nuclear and cell division during which the duplicated chromosomes are divided equally

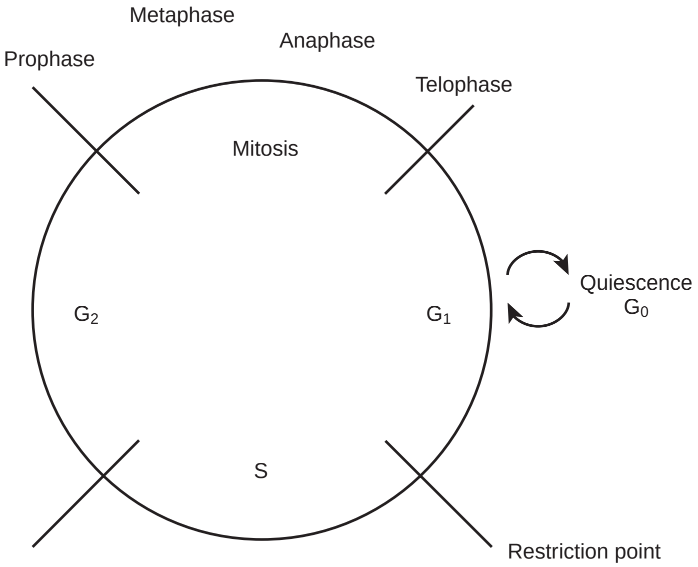

Figure 17.1 THE CELL DIVISION CYCLE. The mammalian cell cycle is divided into 4 phases that include mitosis (M), DNA synthesis (S), and the gap phases G1 and G2. Mitosis is subdivided into prophase, metaphase, anaphase, and telophase. Quiescence (G0) is a non-proliferative state in which viable cells have left the cell cycle and may remain for prolonged periods. A particularly important point in G1 is the restriction point, or R, which occurs near the G1–S boundary. After the cell passes the G1/S restriction point, it is committed to cell cycle progression.

between two progeny cells. It is obvious microscopically as the period of chromosome condensation and segregation, nuclear division (karyokinesis), and physical separation of the two daughter cells (cytokinesis). A cell entering the M phase has a 4 N DNA content and finishes as two cells, each with an identical 2 N complement of DNA. The complex sequence of changes that take place allows mitosis to be subdivided into prophase, prometaphase, metaphase, anaphase, and telophase. *Prophase* is the period of chromatin/chromosome condensation, centrosome separation/migration to opposite poles, and nuclear membrane breakdown. The centrosomes are microtubule organization centers that eventually give rise to the bipole mitotic spindle apparatus that will separate the sister chromatids of each duplicated chromosome. During *prometaphase*, chromosomes attach to microtubules of the mitotic spindle so that sister chromatids attach to opposite poles. In *metaphase*, the condensed chromosomes align at the equatorial plate. The cohesive "bond" between sister chromatids of duplicated chromosomes is dissolved, allowing *anaphase*, the period of sister chromatid separation, to proceed. On reaching their poles, nuclear membranes form to envelop each of the two separated sets of chromosomes, which also begin to decondense, marking *telophase* and karyokinesis. This is immediately followed by cytokinesis, during which an actin-myosin ring at the cell membrane contracts to move inwards until a midbody structure is formed. The abscission of the midbody marks the exit from mitosis. Following mitosis, cells reenter G1, and for approximately 3 hours, they are capable of leaving the cell cycle into quiescence when growth factors and nutrients are missing. Once past this point, cells are no longer sensitive to mitogen withdrawal and can commit to another round of cell division.

SIGNALING

To decide whether to proliferate, cells scan their environment with the help of cell surface receptors such as receptor tyrosine kinases (RTKs) that bind extracellular ligands and activate signaling pathways. RTKs become activated by ligand-stabilized dimerization that allows autophosphorylation.[2] The intracellular phosphotyrosine residues are recognized by SH2 (Src homology 2) or PTB (phosphotyrosine-binding) protein domains, leading to the recruitment of signaling effectors and formation of signaling complexes. In turn, these complexes permit activation of signaling pathways, such as rat sarcoma virus (RAS)–mitogen-activated protein kinase (MAPK), PI3K, and phospholipase Cγ (PLCγ). Together, these signaling pathways stimulate cell proliferation (Fig. 17.2).

T-Cell Receptor

Activation of T cells occurs upon ligation of the T-cell receptor (TCR) by major histocompatibility complex (MHC) molecules in antigen-presenting cells.[3] The TCR and its coreceptors CD4 and CD8 have no intrinsic enzymatic activity. Instead, the associated non–RTK LCK (lymphocyte-specific protein tyrosine kinase) binds to cytoplasmic domains of TCR coreceptors CD4 and CD8, and their activation leads to phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAMs) in CD3. Phosphorylated CD3 recruits the tyrosine kinase zeta-chain-associated protein kinase 70 (ZAP70), leading to a cascade of phosphorylation events that in turn activates LAT (linker for activation of T cells) complexes. The LAT signalosome triggers the release of intracellular Ca^{2+} and the production of diacylglycerol (DAG). The latter activates RAS-MAPK and protein kinase C (PKC)–nuclear factor κB (NF-κB) signaling pathways.

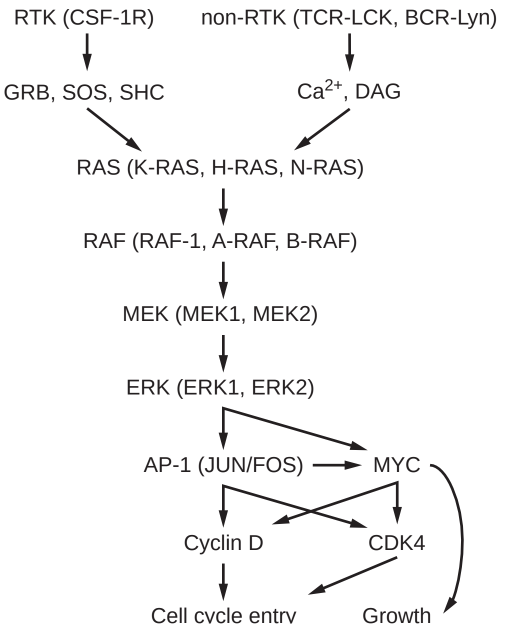

Figure 17.2 SIGNALING PATHWAYS, SUCH AS THE RAS-MAPK PATHWAY, CONTROL CELL CYCLE ENTRY. (See text for details and names of abbreviated items.) Cells scan their environment with the help of cell surface receptors such as receptor tyrosine kinases (RTKs). When RTKs become activated by ligand-stabilized dimerization, they can induce signaling pathways, in this case by activating GRB, SOS, SHC. Alternatively, a non-RTK receptor, like TCR-LCK or BCR-Lyn, can activate RAS by a pathway involving calcium influx and DAG. The RAS-MAPK signaling pathway plays a particularly important role in proliferation. RAS GTPases are activated by many receptors, such as TCR, BCR, and CSF-1R, and recruit MAPK complexes. These complexes are formed by scaffolds, such as KSR, binding to the three-tier MAPK module that comprises RAF, MEK, and ERK. When activated by RAS (H-RAS, K-RAS, N-RAS), the MAPKKK RAF (RAF-1, A-RAF, B-RAF) phosphorylates the MAPKK MEK (MEK1, MEK2), which in turn phosphorylates the MAPK ERK (ERK1, ERK2). Activated ERK kinases phosphorylate the transcription factors MYC and AP-1 (JUN/FOS), leading to transcription activation of Cyclin D1, CDK4, and CDK6. Monophosphorylation of retinoblastoma protein (RB) by Cyclin D-CDK4/6 is required for cells to leave quiescence and enter the cell cycle.

B-Cell Receptor

Every normal B cell has a unique B-cell receptor (BCR) consisting of pairs of immunoglobulin heavy (IgH) and light (IgL) chains. Each IgH and IgL has a unique variable region that allows the BCR to recognize and bind to diverse antigens, both soluble and on the surface of antigen-presenting cells. Antigen-induced aggregation of BCR leads to phosphorylation of ITAMs by the Src family tyrosine kinase LYN. This phosphorylation event initiates the assembly of intracellular signaling molecules, including SYK, PLCγ2, Bruton tyrosine kinase (BTK), VAV, and the adaptor B-cell linker (BLNK). The BCR coreceptor CD19 is also phosphorylated by LYN, leading to the recruitment of PI3K, BTK, and AKT.[4] Together, this signaling leads to the release of intracellular Ca^{2+} and production of DAG, and ultimately leads to activation of RAS-MAPK and PKC–NF-κB signaling pathways.

Macrophage Colony-Stimulating Factor Receptor

The known ligands of macrophage colony-stimulating factor 1 receptor (CSF-1R) are CSF-1 and interleukin (IL)-34.[5] CSF-1 was the first hemopoietic growth factor to be isolated, and it can promote the growth of pure colonies of macrophages from bone marrow progenitors. CSF-1R is an RTK that belongs to the platelet-derived growth factor family. The binding of CSF-1 or IL-34 to CSF-1R leads to dimerization of CSF-1R, which allows autophosphorylation. Numerous proteins, such as GRB2, SOS, SFK, CBL, and p85, are recruited to the intracellular domain phosphotyrosines, leading to the activation of the PI3K-AKT and RAS-MAPK pathways, among others.

RAS Pathway to Cyclin D

The RAS-MAPK pathway is evolutionarily conserved and controls many fundamental processes, including cell proliferation. RAS guanosine triphosphatases (GTPases) are activated by many receptors, such as TCR, BCR, and CSF-1R, and recruit MAPK complexes. These complexes are formed by scaffolds, such as KSR (kinase suppressor of RAS), binding to the three-tier MAPK module that comprises RAF, mitogen-activated protein kinase (MEK), and extracellular signal-regulated kinase (ERK). When activated by RAS (H-RAS, K-RAS, N-RAS), the MAPKKK RAF (RAF-1, A-RAF, B-RAF) phosphorylates the MAPKK MEK (MEK1, MEK2), which in turn phosphorylates the MAPK ERK (ERK1, ERK2). The principal function of RAS in cell cycle induction is to inactivate retinoblastoma protein (RB), relieving cells from its growth-inhibitory actions.[6] The RAS-MAPK signaling pathway is required to induce complexes of cyclin D1 and CDK4/CDK6. Activated ERK kinases phosphorylate the transcription factors MYC and activator protein 1 (AP-1), leading to transcription activation of cyclin D1, CDK4, and CDK6. Notably, PI3K-AKT and PKC–NF-κB pathways cooperate with RAS-MAPK in activating cyclin D1. Mono-phosphorylation of RB by cyclin D–CDK4/6 is required for cells to leave quiescence and enter the cell cycle. Given the important functions of RAS-MAPK signaling in cell proliferation, it is not surprising that cancer hijacks this pathway: K-RAS, N-RAS, and B-RAF are frequently mutated in cancer, leading to constant activation of the RAS-MAPK pathway.

CYCLINS AND CYCLIN-DEPENDENT KINASES

The 2001 Nobel Prize in Physiology or Medicine was awarded for discoveries concerning the control of the cell cycle: Leland Hartwell, Tim Hunt, and Paul Nurse discovered CDKs and cyclins that regulate the cell cycle. Identification and subsequent functional analysis of the factors and cofactors involved in mammalian cell cycle regulation have led to the current view that progression through the cell division cycle is driven by CDKs. These serine/threonine protein kinases play an essential role in promoting the cell division cycle.[7] There are many cyclins and CDKs, but only a limited number directly contribute to promoting cell cycle entry and progression (Fig. 17.3). Typically, the cyclin component binding to the CDK activates the kinase activity. Additionally, the cyclin component provides specificity to the substrate. During the G1 phase, cyclin D (cyclin D1, D2, or D3) binds to either CDK4 or CDK6. The principal targets of cyclin D–CDK4/6 are RB and the RB-related protein p130, which become monophosphorylated by cyclin D–CDK4/6.[8] Unphosphorylated and monophosphorylated RB can bind to the activating E2F (E2F1–E2F3) transcription factors and block E2F-dependent gene expression. In accordance with the important functions of cyclin D–CDK4/6 complexes in leaving quiescence and entering the cell cycle, they are frequently found overexpressed or mutated in some cancers. At the G1- to S phase transition, E-type cyclins (E1 and E2) bind to and activate CDK2, which promotes multiple phosphorylations (hyperphosphorylation) of RB and dissociation of RB from E2F. Consequently, E2F-dependent gene expression is enabled, leading to the expression of genes that encode for proteins required for DNA replication. Cyclin A binds to CDK2 at the end of the S phase and promotes entry into mitosis. CDK2 bound to cyclin E and cyclin A can phosphorylate multiple targets that contribute to DNA replication and cell cycle progression during S and G2 phases. Finally, cyclin B (B1 and B2) associates with CDK1 (CDC2) and contributes to the phosphorylation of many cellular proteins, driving cells through mitosis.

Control of cyclin-CDK activity occurs at many levels. First is the appearance and disappearance of different cyclins at specific phases of the cell cycle, which dictates the cyclin–CDK complexes that can form in each phase. Regulation at this level is a result of highly regulated synthesis and degradation of cyclin messenger RNA (mRNA) and protein at different points in the cell cycle. A second level of regulation is afforded by posttranslational modification of CDK kinases, which is often necessary to activate their function. Cyclin B–CDK1 complexes, for example, are initially inhibited by WEE1 kinase and are activated by CDC25C phosphatase when cells enter mitosis. A third level of regulation is provided by proteins that inhibit the activity of CDK kinases or cyclin-CDK complexes (see later).

Additional kinases and substrates that contribute to cell cycle progression include DDK (Dbf4-dependent kinase), PLKs (polo-like kinases), and Aurora kinases. The DDK CDC7, together with cyclin E–CDK2, coordinates the initiation of DNA replication. The polo-like kinase PLK1 activates, among others, CDC25C and deactivates WEE1, leading to active cyclin B–CDK1 complexes that drive mitosis, and PLK4 regulates centriole biogenesis during mitosis. Aurora kinases coordinate mitotic progression through phosphorylation of multiple proteins that function in chromosome segregation and cytokinesis.

CYCLIN-DEPENDENT KINASE INHIBITORS

Sharp control of CDK activity is achieved by two major classes of small polypeptide CDK inhibitors: the INK4 family (inhibitors of CDK4) comprising p16 (INK4A), p15 (INK4B), p18 (INK4C), and p19 (INK4D); and the CIP/KIP (CDK-interacting protein/kinase inhibitor protein) family that comprises p21 (CDKN1A), p27 (CDKN1B), and p57 (CDKN1C).[9] All members of the INK4 family specifically bind to CDK4 and CDK6, inhibiting their kinase activity by competing with their association with cyclin D. In contrast, CDK inhibitors of the CIP/KIP family bind to cyclin–CDK complexes and disturb their activities.

The first inhibitor to be identified and cloned in mammalian cells was p21 (CIP1, CDKN1A), which binds several different cyclin–CDK complexes. The proteins p27 (Kip1) and p57 (Kip2) were subsequently identified as CDK inhibitors with structural and functional similarities to p21. The regulation of p21 expression sheds light on its function:[10] Expression is transcriptionally induced by p53, the tumor suppressor protein activated by DNA damage, and induction of p21 expression provides a mechanism for halting cell proliferation

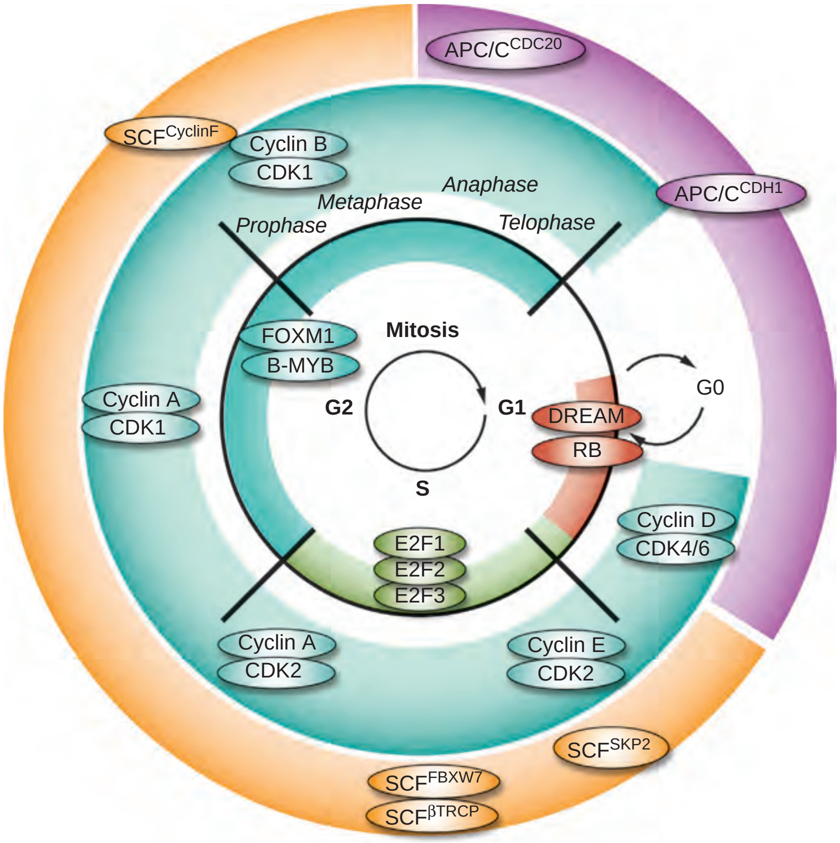

Figure 17.3 A MULTILAYERED NETWORK CONTROLS THE CELL CYCLE. Many proteins that carry out important functions during the cell cycle are encoded by genes that display a periodic expression pattern during the cell cycle. In G0 and early G1, DREAM and RB complexes repress the expression of cell cycle genes. In the late G1 and S phase, RB releases the activating E2F transcription factors that upregulate G1/S cell cycle genes encoding for important proteins in the process of DNA replication. When the S phase is completed, E2F7 and E2F8 will replace E2F1-3 and serve to repress the expression of the G1/S genes. In G2 and mitosis, B-MYB and FOXM1 transcription factors bind to the MuvB core and promote the expression of G2/M genes that encode important proteins for cell division. These transcription factors, as well as many other important cell cycle effectors, are controlled through phosphorylation by Cyclin-CDK complexes. Cyclin D-CDK4/6 complexes promote cell cycle entry and progression through the G1 phase. Cyclin E-CDK2 complexes stimulate S phase entry and progression, and Cyclin A-CDK2 complexes facilitate S phase completion. Cyclin A-CDK1 complexes promote G2 phase progression, and Cyclin B-CDK1 complexes regulate mitosis. These proteins are targets of an additional layer of cell cycle control that mediates their proteasomal degradation. APC/C$^{\text{CDH1}}$ becomes activated in anaphase and promotes exit from mitosis, and ensures proper G1 phase progression. SCF$^{\text{SKP2}}$ functions in the late G1 and early S phase, while SCF$^{\text{betaTRCP}}$ and SCF$^{\text{FBXW7}}$ are active throughout the S phase. SCF$^{\text{Cyclin F}}$ stimulates mitosis entry, and APC/C$^{\text{CDC20}}$ promotes progression through mitosis. Importantly, SCF, APC/C, and Cyclin-CDK complexes also regulate each other, and all these complexes contain effector proteins that are transcriptionally regulated by RB-E2F and MuvB complexes. This multilayered network ensures precise control of the cell cycle. (See text for names of abbreviated items.)

after DNA damage to allow time for damage assessment and repair. The p21 protein also can be expressed in cells lacking functional p53, indicating that p53-independent pathways of expression exist. These other pathways may account for increased p21 expression in other circumstances associated with cell cycle arrest, such as terminal differentiation. p21 inhibits cell cycle progression primarily through the inhibition of CDK2 activity: RB pocket proteins lose their hyperphosphorylated state, leading to the formation of RB-E2F and DREAM (dimerization partner, RB-like, E2F, and multivulva class B) complexes and downregulation of cell cycle genes. Interestingly, p21 promotes the formation of cyclin D–CDK4/6 complexes, and the resulting RB mono-phosphorylation is required for RB function in the DNA damage response program.[8] Inversely, cyclin D-CDK4/6 can sequester p21, preventing the inactivation of CDK2-containing complexes.

In marked contrast to the transcriptional regulation of p21, regulation of p27 (KIP1, CDKN1B) occurs post-transcriptionally, such that mRNA levels remain largely constant, whereas levels of the protein change. p27 protein levels are maximal during quiescence and early G1, and p27 protein binds and inhibits cyclin E–CDK2 complexes. The progressive decrease in p27 protein levels during G1 allows for activation of cyclin E–CDK2 complexes that are required for the transition into the S phase. Notably, to the end of the G1 phase, active cyclin E–CDK2 complexes phosphorylate p27, causing its ubiquitin-mediated degradation and leading to a dramatic decline in p27 protein levels. In accordance with the ability of p21 and p27 to inhibit cyclin-CDK activity and cell cycling, *p21* and *p27* are candidate tumor suppressor genes, but silencing or loss of these genes is very uncommon in cancers. Unlike its ubiquitous siblings, p57 has a tissue-specific expression pattern during embryogenesis and, in the adult, it is the only CDK inhibitor required for embryonic development.

Striking diversity in the pattern of expression of *INK4* genes suggests that this family of CDK inhibitors might have cell type–specific or tissue-specific functions. The two founding members, p16 and p15, were cloned as tumor suppressor genes, and the p18 and p19 proteins were subsequently cloned on the basis of homology to p16 and p15. INK4 CDK inhibitors block CDK4 and CDK6, and as RB family proteins are prime targets of cyclin D–CDK4/6 kinase, phosphorylation of these proteins is crucial for G1 progression; the INK4 inhibitor family induces cell cycle arrest in G1. Evidence that INK4 proteins inhibit cell proliferation by preventing phosphorylation of RB pocket proteins is provided by the observation that p16 overexpression inhibits proliferation only of cells containing functional RB pocket protein. p16 and p15 CDK inhibitors are inactivated by mutations in various cancers, providing evidence for their function as tumor suppressors. Importantly, p16 and p15 are neighboring genes on chromosome 9, and *CDKN2A*, the gene encoding for p16, also encodes for ARF using an alternative reading frame that produces a totally different protein. This overlap means that inactivating mutations affect p16 and ARF function. Because ARF is a positive regulator of p53 expression and a tumor suppressor protein in its own right, attribution of a tumor suppressor effect to each of these two genes is difficult. An interesting aspect of p16 expression is its upregulation in aging tissues and in response to oncogene activation. For example, in response to continuously high RAS or E2F activity, *CDKN2A* is transcriptionally induced, leading to cell cycle arrest and senescence.

TRANSCRIPTIONAL REGULATION: MYC, RB-E2F, AND DREAM/MUVB

Cell cycle entry and progression require specific genes to be expressed at certain times. When cell proliferation is triggered by growth conditions and cells leave quiescence, mitogen signaling leads to the activation of the MYC transcription factor.[1] MYC has the capability to drive cell proliferation because it activates cyclin D and CDK4/6, and it plays an important role in cell growth because it upregulates ribosomal RNA and proteins, leading to increased ribosome biogenesis and translation. Indeed, experiments showed that when MYC is missing, cell growth and proliferation slow down, and cells arrest primarily in the G1 phase. MYC activity ensures that cells reach a certain size before entering the S phase and progressing through the cell cycle.

The two main cell cycle events—DNA synthesis and mitosis—take place after the cell passes the G1/S restriction point and is committed to cell cycle progression. Entry into the S phase requires the expression of genes required for DNA replication. These genes are distinct from the ones required for entry into mitosis. In general, there are two major waves of gene expression, one occurring just before entry into the S phase and a second wave occurring just before entry into mitosis (see Figs. 17.3 and 17.4). The periodic expression of mRNA produces the specific protein factors required for DNA replication and cell division. Once the S phase is completed and cells have passed through mitosis, many of these protein factors are ubiquitinated and degraded by the proteasome, thereby ensuring one-way progression through the S and M phases of the cell cycle.

Proliferating cells require the expression of specialized genes for the synthesis of DNA during the S phase and for cell division during mitosis. These cell cycle–dependent genes are not typically required for the survival of quiescent cells. The expression of more than 1000 cell cycle–dependent genes is nearly absent during quiescence in G0 cells. For the most part, the expression of these cell cycle–dependent genes is silenced by the *trans*-repressor complexes DREAM and RB-E2F.[11] The DREAM complex is a multi-subunit protein complex that binds to promoters of cell cycle–regulated genes and contributes to their repression. The DREAM complex is comprised of the RB-like protein p130 (RBL2), E2F4 or E2F5, DP1 or DP2, and the 5-component MuvB complex containing LIN9, LIN37, LIN52, LIN54, and RBBP4.[12] Whereas the DREAM complex contributes to the expression of both S phase– and M phase–specific genes, the RB protein specifically represses S phase–specific genes.[13] RB binds to the activating E2F transcription factors (E2F1–E2F3) and blocks E2F-mediated activation of S phase genes. S and M phase genes possess distinct promoter elements that mediate the binding of RB-E2F and DREAM complexes. E2F promoter elements contain the canonical DNA sequence TTTCGCGC and specifically mediate binding of E2F transcription factors in S phase genes. In contrast, M phase genes possess cell cycle genes homology region (CHR) promoter elements that comprise the canonical DNA sequence TTTGAA and specifically mediate the binding of the MuvB complex.[14]

When a quiescent cell is stimulated to enter the cell cycle, it begins to express cyclin D that binds to CDK4 or CDK6 and is capable of

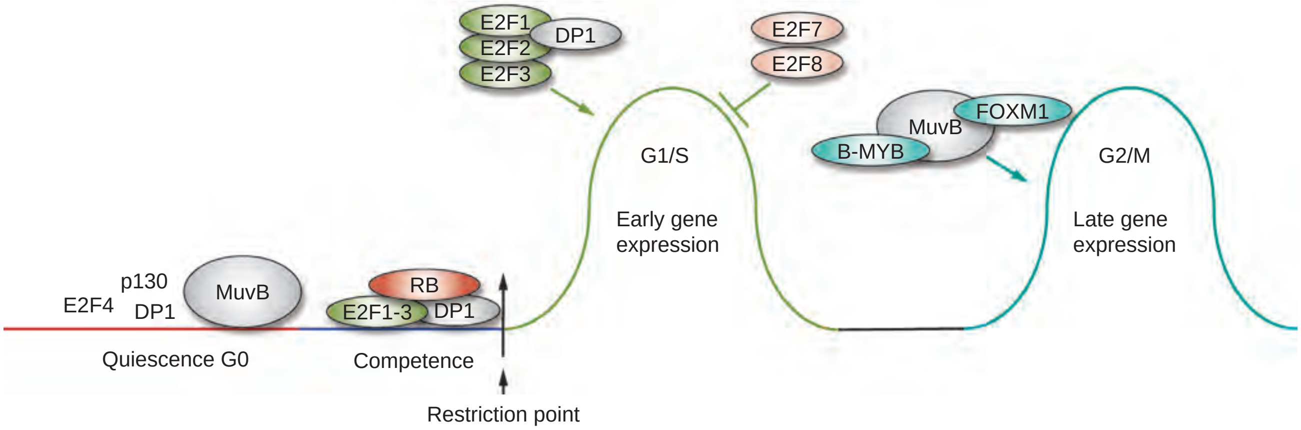

Figure 17.4 TRANSCRIPTION CONTROL OF G1/S AND G2/M CELL CYCLE GENES. There are two major waves of gene expression, with one occurring just prior to entry into the S phase and a second wave just prior to entry into mitosis. The DREAM complex represses both early and late cell cycle gene expression during quiescence *(red line)*. RB binds to the activating E2F transcription factors (E2F1–3) and blocks E2F-mediated activation of S phase genes. In the late G1 phase and S phase, the activating E2Fs dimerize with DP1 or DP2, bind to the promoters of genes required for DNA synthesis through E2F promoter elements, and promote their expression. During the late S phase, E2F7 and E2F8 will replace E2F1–3 and serve to repress the expression of the G1/S genes when DNA synthesis is completed. The B-MYB transcription factor binds to the MuvB core when p130, E2F4, and DP are released from the DREAM complex. The MMB complex recruits FOXM1 to promote the expression of genes in the late G2 phase and M phase.

monophosphorylating RB. In the late G1 phase, Cyclin E–CDK2 complexes multi-phosphorylate the monophosphorylated RB, leading to the release of the activating E2F transcription factors.[8] The activating E2Fs dimerize with DP1 or DP2, bind to the promoters of genes required for DNA synthesis through E2F promoter elements, and promote their expression during the late G1 phase and S phase. These G1/S genes encode many of the factors required for DNA replication. During the late S phase, E2F7 and E2F8, which are E2F targets themselves, will replace E2F1–E2F3 and serve to repress the expression of the G1/S phase genes when DNA synthesis is completed.

Cyclin D–CDK4/6 and cyclin E–CDK2 are also capable of phosphorylating p130, thereby enabling the release of p130 from the DREAM complex. The B-MYB (MYBL2) transcription factor is encoded by a G1/S gene and binds to the MuvB core when p130, E2F4, and DP are released from the DREAM complex. The newly formed MMB (B-MYB–MuvB) complex does not contain any E2F transcription factor and thus binds exclusively to genes that possess CHR promoter elements. These genes are highly expressed in late G2 phase and M phase and encode for proteins that carry out essential functions in mitosis. The MMB complex recruits FOXM1, a third transcription factor, to promote the expression of these G2/M genes. Notably, *FOXM1* is a G2/M gene itself, and together with the important role of FOXM1 in promoting the expression of G2/M genes, *FOXM1* has emerged as one of the most robust biomarkers for stratifying high-risk and low-risk cancers.[15] The B-MYB and FOXM1 factors are ubiquitinated and destroyed by the proteasome during late mitosis, resulting in a decrease in expression of the G2/M genes when a cell exits mitosis. Therefore the DREAM complex represses all cell cycle genes during quiescence, with the G1/S cell cycle genes being activated by E2F1–E2F3 and the G2/M late cell cycle genes being activated by B-MYB–MuvB–FOXM1.

Together, proliferation signals will enable MYC-dependent gene expression that contributes to the growth in the size of the cell, whereas the E2F and B-MYB/FOXM1-dependent gene expressions induce genes required for DNA replication during the S phase and cell division during mitosis. Given the strong link between the expression of cell cycle-regulated genes and cell proliferation, cell cycle genes have prognostic value for stratifying cancers because malignancy correlates with the number of proliferating cells in a tumor.[16]

UBIQUITINATION

Cells employ a variety of mechanisms to control the cell division cycle, ensuring one-way progression through S and M phases of the cell cycle. Cell cycle genes are periodically expressed at certain times, and cyclin-CDK complexes drive the cell cycle through the control of the cell cycle transcription machinery and regulation of critical events in S and M phases. The mRNA of many cyclins and CDKs is also cell cycle–dependently regulated, and in addition, cyclin-CDK activity is regulated by CDK inhibitors. Yet, cells employ an additional layer of cell cycle control through the timed destruction of essential cell cycle proteins, including cyclins, CDKs, and cell cycle transcription factors (see Fig. 17.3). Two ubiquitin ligases, the Skp, Cullin, F-box–containing complex (SCF) and the anaphase-promoting complex/cyclosome (APC/C), are responsible for the specific ubiquitination of many of these cell cycle proteins.[17] The SCF complex consists of the three invariable components RBX1, CUL1, and SKP1. RBX1 is a RING finger protein that functions as an E3 ubiquitin ligase, CUL1 is a scaffold protein, and SKP1 is an adaptor protein. In addition to the three invariable components, one variable coactivator, known as an F-box protein, binds through its F-box motif to SKP1 and is responsible for substrate recognition. Approximately 70 putative F-box proteins have been identified in humans, and at least four of them are thought to be involved in cell cycle control: SKP2, FBXW7, β-transducin repeats-containing proteins (β-TRCP), and cyclin F. The SCF complex mediates the degradation of cell cycle proteins during the progression from the late G1 phase through the S phase until the onset of mitosis. Important substrates include cyclin D and cyclin E; the transcriptional regulators MYC, E2F1, and p130; the CDK inhibitors p27 and p21; and WEE1 kinase. WEE1 kinase deactivates cyclin B–CDK1 complexes. Degradation of these important cell cycle regulators allows for proper S phase entry and the completion and onset of mitosis.

The APC/C complex consists of several invariable components, and the central ones are structurally similar to the SCF complex components. APC11 is a RING-finger protein related to RBX1, and APC2 is a scaffold protein related to CUL1. Similar to the SCF complex, APC/C contains a variable coactivator that confers substrate specificity. Two of such variable coactivators function in the cell cycle: CDC20 and CDH1. APC/C^{CDC20} mediates the degradation of substrates during mitosis, whereas APC/C^{CDH1} functions primarily in the G1 phase. Key substrates of APC/C^{CDC20} are cyclin A and cyclin B. With the onset of anaphase, activation of APC/C^{CDH1} leads to the degradation of CDC20, PLK1, and Aurora kinases.

Similar to the other cell cycle control systems, SCF and APC/C are controlled within the cell cycle, in part by their own substrates. Most important, SCF and APC/C can regulate each other. The cell cycle protein FBXO5 (EMI1) functions as an inhibitor of APC/ C^{CDC20} and is sent to proteasomal degradation by $SCF^{\beta\text{-TRCP}}$ when mitosis starts, and $SCF^{\text{cyclin F}}$ mediates degradation of CDH1. Similarly, ubiquitination of CDC20 and cyclin F by APC/C^{CDH1} leads to their destruction when cells exit mitosis. Further regulation occurs on the transcriptional level because substrate-specific components of SCF and APC/C are encoded by cell cycle–regulated genes, including *SKP2*, *FBXO5*, *Cyclin F*, and *CDC20*.

DEOXYRIBONUCLEIC ACID REPLICATION

The initiation of DNA replication represents a commitment to cell proliferation and is a central event in the growth and division of all organisms.[18] The assembly of replication machineries is coordinated by multiple proteins, which ensure that DNA synthesis begins at the correct chromosomal locus. Strict regulation of initiation is crucial to viability because inappropriate replication start is linked to genetic instability, including alterations in gene copy number and DNA damage. DNA replication starts with the assembly of prereplication complexes (pre-RCs) at multiple DNA replication origins during the G1 phase. At the transition from G1 to S phase, the replicative helicase is activated, leading to a change from pre-RCs to preinitiation complexes, which unwind DNA and initiate DNA synthesis. The recognition of pre-RC sites is known as replication origin licensing, and the activation of DNA synthesis is known as origin firing. The separation of these two steps is critical for preventing re-replication within the same cell cycle.

Replication origin licensing in the G1 phase involves the sequential assembly of different proteins. The origin recognition complex (ORC) consists of the six subunits ORC1–ORC6 and initially binds to replication origins. Then, CDC6 and CDT1 associate with the ORC, leading to the recruitment of the minichromosome maintenance (MCM) complex, which consists of six subunits: MCM2–MCM7. The MCM complex is a helicase that forms a double hexamer and encircles double-stranded DNA. Together, the inactive assembly of ORC, CDC6, CDT1, and MCM is known as the pre-RC. Notably, the Meier-Gorlin syndrome, a form of primordial dwarfism, is linked to mutation or depletion of pre-RC components, which impairs cell cycle progression.

During the transition from G1 to S phase, the MCM complex is phosphorylated by CDC7 and cyclin E–CDK2, leading to the recruitment of CDC45 and the four-protein DNA replication complex GINS. Together, CDC45, MCM, and GINS represent the CMG complex, and dissociation of the two MCM hexamers enables the formation of two preinitiation complexes at a replication origin. Cyclin E–CDK2 phosphorylates Treslin (TICRR) and RECQL4 that, with TOPBP1 and MCM10, facilitate the formation of the preinitiation complex. After replication origins are licensed, ORC1 phosphorylation by cyclin A–CDK1 inhibits rebinding of ORC1 to replication origins, and CDT1 is blocked by Geminin (GMNN) and sent to proteasomal degradation by SCF^{SKP2} to prevent relicensing during the S phase.

In the S phase, initiation of DNA replication by CDK2 promotes helicase activation, which leads to the unwinding of DNA and recruitment of DNA polymerases alpha (POLA), delta (POLD), and epsilon (POLE), together with PCNA (proliferating cell nuclear antigen) and RFC (replication factor C). The MCM complex translocates from replication origins to unwind double-stranded DNA, whereas POLA binds to single-stranded DNA and initiates DNA synthesis on both the leading and lagging strands by providing an RNA primer and synthesizing the first bases of DNA. POLE and POLD elongate these primers with a base substitution error rate of approximately 10^{-5}. When they occasionally incorporate a false nucleotide, it is usually removed by an exonuclease associated with these DNA polymerases. This so-called proofreading, together with DNA mismatch repair mechanisms, leads to mutation rates of as low as 10^{-9} per base and per cell division cycle.

An immediate consequence of DNA replication is the disruption of chromatin in front of the replication fork, which results in the release of parental histones. When the replication fork has passed, chromatin is rapidly reassembled onto old as well as newly replicated DNA, and in the reassembled chromatin, half of the histones are recycled from the parental chromatin, whereas the other half are newly synthesized.[19] Then, the multiprotein complex cohesin mediates cohesion between replicated sister chromatids in the S phase, which is essential for chromosome segregation in the M phase.

In addition to DNA replication, the centrosome also needs to be replicated to allow the formation of two daughter cells.[20] The centrosome is the major microtubule-organizing center and consists of two centrioles. Phosphorylation by cyclin E–CDK2 promotes the formation of one procentriole at each centriole. During S and G2 phases, procentrioles elongate until they reach the length of the older centrioles. In the early M phase, the two centrosomes separate to promote cytokinesis.

MITOSIS

The decision to enter mitosis is mediated by a network of proteins that regulate activation of the cyclin B–CDK1 complex.[21] In principle, a feedback system between CDK1, WEE1/CDC25C, and the CDK1-counteracting phosphatases generates a bistable switch, leading to robust directionality that prevents cells from going back and forth between G2 and M phases. Cyclin B and CDK1 levels increase in the late S phase and G2 phase, and the activity of newly made cyclin B–CDK1 complexes is blocked through phosphorylation by WEE1. Activation of the cyclin B–CDK1 complex is the key to cell entry into mitosis and occurs just before mitosis through the action of CDC25C, causing dephosphorylation of CDK1. The activities of WEE1 and CDC25C are themselves regulated with phosphorylation, inhibiting WEE1 function and enhancing CDC25C function. Once a small amount of cyclin B–CDK1 is activated, it can phosphorylate CDC25C and create a self-amplifying feedback loop that generates more active cyclin B–CDK1 from the large preexisting stock of inactive complex. What starts this sequence of events by initially phosphorylating and activating CDC25C is unclear, but PLK1 is a candidate kinase that can phosphorylate WEE1, CDC25C, and cyclin B, leading to nuclear localization of cyclin B and CDC25C. Cyclin B–CDK1 can phosphorylate serine/threonine residues in many cellular proteins that are essential for mitosis. Phosphorylation of lamins by cyclin B–CDK1 promotes nuclear lamina disassembly and envelope breakdown, which occurs during prophase. Phosphorylation of some kinesin motor proteins that function in spindle assembly, such as KIF11 and CENPE, by cyclin B–CDK1 increases their efficiency of microtubule binding and increases processive motility along microtubules. Other kinesins that function in midzone formation, such as KIF23, are blocked in their activity by cyclin B–CDK1–mediated phosphorylation.

After chromosome condensation, centrosome separation, and nuclear envelope breakdown during prophase, chromosomes attach to microtubules of the mitotic spindle apparatus in prometaphase. Kinetochores were originally called *centromeres* because they are located at the center of chromosomes. They are formed by centromere proteins during the G2 phase and prophase and link chromosomes to the mitotic spindle apparatus so that sister chromatids become attached to opposite poles. In metaphase, the chromosomes align at the equatorial plate, and cyclin B–CDK1 levels start to decline by APC/CCDC20-mediated degradation of cyclin B. The APC/CCDC20 further targets securin (PTTG1) and thereby activates separase (ESPL1), which cleaves the cohesin complexes linking sister chromatids. Once CDK1 activity is low, APC/CCDH1 becomes active and removes CDC20, PLK1, and Aurora kinases, as well as the mitotic cyclins and CDKs.

In anaphase, the spindle midzone forms between the separating chromosomes by coordinated actions of the microtubule cross-linker PRC1, the kinesin KIF4, and the multiprotein complexes centralspindlin and CPC (chromosomal passenger complex).[22] Centralspindlin consists of the kinesin KIF23 and the Rho GTPase RACGAP1, and the CPC consists of Aurora kinase B, the scaffold INCENP, survivin (BIRC5), and CDCA8. Phosphorylation by CPC promotes recruitment of centralspindlin to the spindle midzone through KIF23 and allows for multimerization and accumulation of centralspindlin, which in turn promotes localization of the RhoGEF ECT2 (epithelial cell transforming 2) to microtubules. ECT2 then fuels RhoA, which promotes the recruitment of effector contractile ring proteins. As the ring closes, the spindle midzone is remodeled to form the densely packed telophase midbody, which organizes the intracellular bridge. At this time in telophase, nuclear membranes form to envelop each of the two separated sets of chromosomes, which also begin to decondense. This is soon followed by the abscission event near the midbody, which completes mitosis.

CELL CYCLE CHECKPOINTS

Competence

Cells require the presence of nutrients and growth factors to switch from quiescence to a state of proliferation. When cells sense that conditions are suitable for proliferation, they leave quiescence into the G1 phase and become competent to enter the cell cycle. G1 has been subdivided into segments and regulatory points based largely on the study of the proliferative response of cells to sequential application of different growth factors, nutrients, and metabolic inhibitors. From the standpoint of cell cycle regulation, a particularly important point in G1 is the restriction point, or R, which occurs near the G1–S boundary. The period after mitosis, when cells can enter quiescence, is termed G1pm (postmitosis), and the period between quiescence and S phase is termed G1ps (pre-DNA synthesis) (Fig. 17.5). Notably, nearly all of the variability in the length of G1 can be accounted for by the G1ps interval. Experiments have shown that, to leave quiescence and to enter the cell cycle, cells require growth signals either continuous for several hours during G1 or, alternatively, as two discrete pulses of approximately 1 hour in duration and with a pause of several hours in between.[20] To become competent for cell cycle entry, initial activation of the MAPK pathway by mitogen signals is required that in turn activates essential metabolic programs. However, this initial increase in MAPK activity does not lead to induction of MYC and cyclin D; it leads only to the presence of growth signals several hours later that activate the PI3K pathway and MYC. Functions of MYC include transcriptional activation of *CDK4* and *Cyclin D*, as well as downregulation of CDK inhibitors. The following increase in cyclin D–CDK4 complex activity leads to phosphorylation of the principal target RB during the G1 phase.

Restriction Point

In 1974, Arthur Pardee published the first report on the restriction point and defined it as a point at which cells become committed to

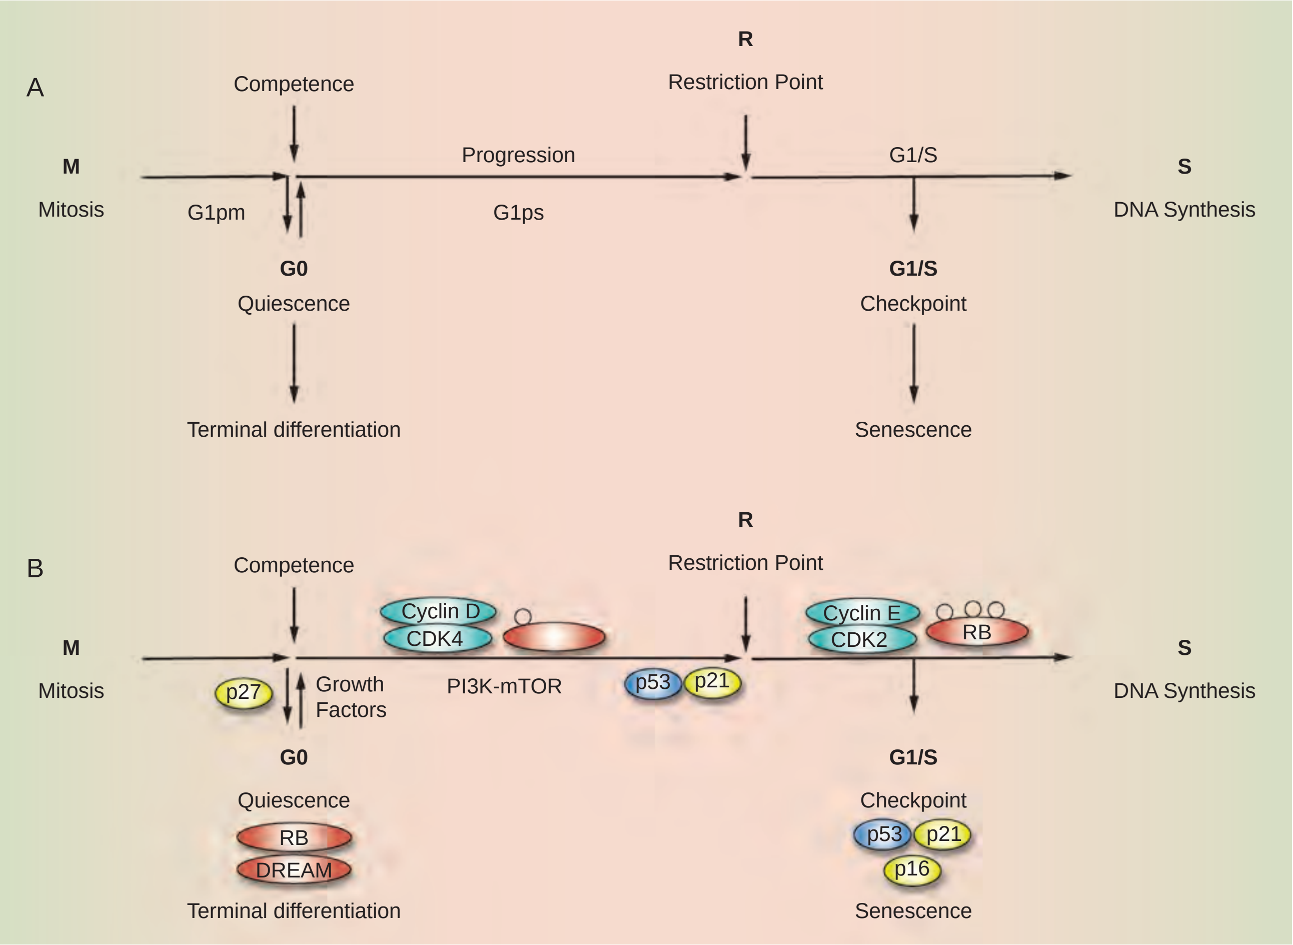

Figure 17.5 CHECKPOINTS OF CELL CYCLE ENTRY. (A) Quiescence is a non-proliferative state in which viable cells have left the cell cycle and may remain for prolonged periods. In contrast, terminally differentiated cells have irreversibly exited the cell cycle during the process of differentiation. When cells sense that conditions are suitable for proliferation, they leave quiescence into the G1 phase and become competent to enter the cell cycle. G1 has been subdivided into segments, and a particularly important point is the restriction point, or R, which occurs near the G1-S boundary. The period after mitosis, when cells can enter quiescence, is termed G1pm (post mitosis), and the period between quiescence and S phase is termed G1ps (pre-DNA synthesis). When DNA damage is recognized in G1, the G1/S checkpoint becomes activated, which blocks cells from S phase entry, although they may have passed the restriction point. If damage is not repaired timely, cells will enter senescence where they remain viable but not capable of re-entering the cell cycle. (B) During quiescence, the CDK inhibitor p27 prevents Cyclin-CDK activity, and DREAM and RB bind and repress cell cycle genes. When prompted by growth signals, cells enter the competent state. Activation of RAS-MAPK and PI3K signaling pathways is followed by activation of Cyclin D-CDK4/6, leading to mono-phosphorylation of RB. The progressive decrease in p27 protein levels during G1 allows for activation of Cyclin E-CDK2, which multi-phosphorylate the mono-phosphorylated RB, leading to the release of the activating E2F transcription factors. When DNA damage is recognized in G1, p53 becomes activated, and the p53 target gene *p21* promotes cell cycle arrest at the G1/S transition through inhibition of Cyclin E-CDK2 and activation of RB. Also, p16 can become activated by oncogenic stress, which leads to inhibition of Cyclin D-CDK4/6 and activation of the G1/S checkpoint. If stress signaling is not relieved, cells will enter a senescent state.

entering the S phase, regardless of subsequent availability of growth factors or essential nutrients.[23] He also correctly predicted that cancer cells undergo changes to become independent from growth factors and the restriction point. In the four decades that have passed since the initial description of the restriction point, many important insights have been gained that revealed the signaling events that contribute to proliferation and growth. In addition to the key contributions of signaling by MAPK, PI3K, and MYC to enable cell growth, it also became clear that there are restraining activities that can inhibit cell cycle entry and progression. As mentioned earlier, cyclin D levels increase during the progression phase of G1, and cyclin D–CDK4/6 complexes monophosphorylate RB, which restricts the activating E2F transcription factors.[8] Later in G1, cyclin E levels increase, and cyclin E binds specifically to CDK2. This leads to RB hyperphosphorylation and release of the activating E2Fs, enabling E2F-dependent gene expression. Once past this point, growth factors are no longer required for S phase entry. Therefore, expression and activation of cyclin E–CDK2 resulting in the hyperphosphorylation of RB enables a cell to pass the restriction point and become committed to cell cycle entry.

G1/S Checkpoint

The G1/S DNA damage checkpoint can be viewed as a point in the cell cycle when the cell has become fully committed to entering into the S phase and past the restriction point but is unable to enter the S phase because cyclin E–CDK2 and cyclin D–CDK4 are inactivated by p21 and p16, respectively, and RB remains capable of binding to and repressing the activating E2Fs, thereby decreasing levels of factors required for DNA synthesis. In G1, DNA damage is recognized by ataxia-telangiectasia mutated (ATM) kinase, which in turn phosphorylates histone variant H2AX to recruit repair factors and CHEK2 kinase.[24] CHEK2-mediated phosphorylation activates p53 and inactivates CDC25A, which is required for the activation of cyclin E–CDK2 complexes. The p53 target genes *p21* and *BTG2* further promote cell cycle arrest at the G1/S transition through inhibition of cyclin E–CDK2 and activation of RB. If the DNA damage or stress signals are repaired, cells can exit the G1/S checkpoint and re-enter the cell cycle.

S Phase Checkpoint

Under conditions that put DNA replication at risk, such as DNA damage or nucleotide depletion, the S phase checkpoint gets activated. Ataxia-telangiectasia and Rad3-related protein (ATR) is the main kinase that senses DNA damage during the S phase, and it phosphorylates CHEK1 kinase, which in turn activates p53. Similar to the G1/S checkpoint, inhibition of cyclin E–CDK2 is central to the S phase checkpoint. The inhibition of CDK2 activity blocks the loading of CDC45 onto replication origins and prevents the initiation of new origin firing. In addition to inhibiting cyclin E–CDK2, p21 directly interacts with PCNA to stop DNA replication. If the damage is repaired, cells continue DNA replication and cell cycle progression.

G2/M Checkpoint

The G2/M checkpoint prevents cells from initiating mitosis when DNA damage occurs during G2 or when cells progress into G2 with some unrepaired damage inflicted during previous S or G1 phases. The G2/M checkpoint also involves DNA damage recognition by ATM and ATR kinases and subsequent p53 activation through CHEK1 and CHEK2 kinases, and it ultimately requires activation of the p21 CDK inhibitor. If p21 is missing, both G1/S and G2/M checkpoints are abolished. In addition to p21, p53 induces GADD45A and 14-3-3 (stratifin (SFN)), which contribute to G2/M cell cycle arrest. 14-3-3 removes essential mitotic regulators from the nucleus and thereby promotes G2/M arrest. Moreover, inhibition of cyclin-CDK activity through p21 induces DREAM and RB-E2F complexes, which in turn repress the transcription of the cell cycle machinery.[11]

Senescence

If damage is not repaired timely, cells will enter a senescent state in which they remain viable but not capable of re-entering the cell cycle. Telomere shortening, which signals cell aging, also is recognized as a type of DNA damage and can trigger senescence.[25] RB is key in establishing the senescent state, which is activated downstream of p53 and the CDK inhibitors p16 and p21. During senescence, cells have committed to proliferation and presumably have passed the restriction point. In contrast to quiescence, senescent cells are unable to re-enter the cell cycle in response to external stimuli, such as growth signals.

Spindle Assembly Checkpoint

The spindle assembly checkpoint (SAC) involves the MAD (mitotic arrest deficient) proteins MAD1, MAD2, BUBR1 (MAD3), and BUB1.[26] To complete mitosis, the cell strictly requires the activity of cyclin B–CDK1. The main effector of the SAC is the mitotic checkpoint complex (MCC), which consists of MAD2, BUBR1, and BUB3 and binds to CDC20, the substrate-specific cofactor of the APC/C that mediates degradation of cyclin B and securin. Inhibition of CDC20 prolongs prometaphase until all chromosomes have become correctly orientated on the metaphase plate. Unattached kinetochores recruit MCC through BUB1, leading to active MCCs. Only when kinetochores are attached correctly to the mitotic spindle is the MCC deactivated, which in turn activates APC/CCDC20 and allows for mitosis progression.

SPECIAL HEMATOLOGY CELL CYCLE FEATURES

Hematopoietic Stem Cells

Hematopoietic stem cells (HSCs) are characterized by their ability to execute multiple cell fate choices, including self-renewal, quiescence, and differentiation into the many different mature blood cell types. The stem cell niche forms the essential microenvironment for HSCs, and the primary HSC niche in adult organisms is located in the bone marrow. Stem cells are quiescent until prompted to proliferate by external stimuli. Stem cell quiescence is achieved largely through the CDK inhibitors p21, p27, and p57.[27] The pool of HSCs contains subsets that differ in self-renewal potential and cell division frequency. So-called short-term HSCs rapidly enter the cell cycle upon mitogen stimulation, whereas long-term HSCs exit quiescence later. This difference can result at least in part from varying CDK6 levels in HSC subsets. The absence of CDK6 in the long-term compared with short-term HSCs can result in a delay in quiescence exit, and the cumulative effect of this delay limits proliferation of these cells and ultimately preserves the long-term integrity of the HSC pool.

Endoreplication

A special type of cell cycle progression is featured in the differentiation of cells that have high metabolic profiles required for the synthesis of specific proteins, such as plasma proteins produced by hepatocytes, or for the production of platelets by megakaryocytes (MKs). Thrombopoietin (TPO) is the major regulator that directs the growth and development of MKs from HSCs. TPO binds to the MK-specific receptor MPL, leading to MPL dimerization and activation of JAK2 (Janus kinase 2). Initially, this signaling leads to endoreplication and accumulation of DNA content of up to well over 128 N before proceeding to final maturation and proplatelet formation.[28] Endoreplication requires impaired cyclin B–CDK1 kinase activity, which is achieved through upregulation of the CDK inhibitor p21 and induction of the APC/C subunit CDH1 after S phase completion. MK endoreplication also requires the prevention of active RhoA through downregulation of ECT2. During the S phase, cyclin E–CDK2 inactivates CDH1 to allow for proper DNA replication. As a result of the following CDK1 inhibition, mitosis is completely bypassed after DNA replication. Inhibition of CDK1 and RhoA and activation of ACP/CCDH1 promote bypass of mitosis and entry into the next G1 phase.

CHAPTER 18

CELL DEATH

Paolo Strati, Marina Konopleva, and William Wierda

CORE APOPTOSIS PATHWAYS

Apoptosis is a biochemically well-defined programmed cell death that is essential for normal development and cellular homeostasis; dysregulation of apoptosis is involved in several diseases. The classical morphological features of apoptosis include cell shrinkage, membrane blebbing, nuclear condensation, and deoxyribonucleic acid (DNA) fragmentation. The biochemical hallmarks of apoptosis include permeabilization of the outer mitochondrial membrane (MOMP), activation of caspases, and the externalization of phosphatidylserine, leading to phagocytosis of the apoptotic remnants without inducing inflammation.

In mammals, apoptosis is initiated by either internal or external stimuli and is governed by two molecular programs that terminate in caspase activation: the intrinsic (mitochondria-mediated) pathway and the extrinsic (death receptor-mediated) pathway. The intrinsic pathway is regulated by B-cell lymphoma (BCL-2) family proteins that determine whether MOMP occurs. Upon MOMP, cytochrome C is released into the cytosol, where it binds apoptotic protease activating factor 1 (APAF-1) and caspase-9 to form the "apoptosome," which in turn cleaves and activates the downstream effectors caspase-3 and caspase-7. Caspases (cysteinyl aspartate–specific protease) are a family of cysteine proteases that function as the central effectors of apoptosis. These executioner caspases cleave multiple cellular substrates, resulting in the nuclear condensation, DNA fragmentation, and membrane blebbing that are characteristic of apoptosis. Other apoptogenic factors released from mitochondria, including apoptosis-inducing factor (AIF), second mitochondria-derived activator of caspase (SMAC)/Diablo, Omi/HtrA2, and endonuclease G, augment intrinsic apoptosis. The extrinsic pathway is initiated upon ligation of the death receptors of the tumor necrosis factor (TNF) receptor family, which recruit the adapter molecule FAS-associated death domain protein (FADD) and then caspases-8 and -10, leading to activation of other downstream caspases. Conventional, nonconventional, and other mechanisms of apoptosis and other modes of cell death are described in detail below (Table 18.1).

THE INTRINSIC APOPTOTIC PATHWAY

The intrinsic apoptotic pathway relies on the BCL-2 family of proteins, which include multiple proteins that share BCL-2-like homology domains 1-4 (BH1-BH4). The BCL-2 family proteins can be classified by their functions: suppressors (BCL2, BCL-XL, BCL-W, BCL2-A1, and myeloid cell leukemia [MCL-1]), activators (BCL2-interacting mediator of cell death [BIM] and p53 upregulated modulator of apoptosis [PUMA]), effectors (BCL2 associated X [BAX] and Bcl-2 homologous antagonist/killer [BAK]), and sensitizers (NOXA).[1,2] Activators and effectors oligomerize, creating pores in the mitochondrial outer membrane. Subsequently, cytochrome C is released through the membrane and caspase-9 activated, ultimately leading to proteolytic cell death. Suppressors bind to and counteract activators and effector, while sensitizers bind directly to suppressors, which causes their disassociation from effector and activator proteins (Fig. 18.1).

The proapoptotic proteins (including activators and effectors) share a homology only in their BH3 domain and have specific interaction with the five anti-apoptotic proteins (or suppressors) outlined above. By exposing mitochondria to known concentrations of BH3 peptides and measuring the resulting MOMP, it is possible to understand the specific antiapoptotic proteins on which a cell depends for its survival. This technique, called BH3 profiling, is considered the most accurate assessment of BCL-2 family member dependence.[3–5]

NONAPOPTOTIC ROLES OF BCL-2 FAMILY PROTEINS

Biochemical evidence indicates that select BCL-2 proteins interact with several non-BCL-2 protein partners that endow them with homeostatic roles beyond regulation of apoptosis. These functions include, but are not limited to, mitochondrial energy and nutrient metabolism, calcium signaling, cell cycle checkpoints, and DNA damage response.[6,7] In addition, several BCL-2 family proteins have been implicated in the regulation of mitochondrial electron transport chain activity in healthy cells that have not been stressed with any apoptotic signals. For example, BCL-XL interacts with the voltage-dependent anion channel protein that mediates ADP/ATP exchange across the mitochondrial membrane and facilitates mitochondrial respiration.[8,9] BCL2 was reported to be upregulated in quiescent leukemia stem cells (LSCs), where it maintains oxidative phosphorylation;[10] in another report, the combination of BCL2 inhibitor venetoclax and the hypomethylating agent azacitidine disrupted the tricarboxylic acid cycle in LSCs by targeting glutathionylation of mitochondrial complex II of the electron transport chain.[11] Proteolytic processing of MCL-1 produces an N-truncated MCL-1 isoform that is localized to the mitochondrial matrix, where it maintains normal inner mitochondrial membrane structure, regulates mitochondrial fusion, and supports mitochondrial bioenergetic functions.[12] This MCL-1 isoform does not have antiapoptotic activity. Furthermore, this inner mitochondrial membrane form of MCL-1 interacts with very-long-chain acyl-CoA dehydrogenase, a key enzyme in the mitochondrial fatty acid oxidation pathway.[13] Understanding the precise molecular mechanisms underlying these nonapoptotic functions is important for effective targeting of these proteins in disease settings.

THE DEATH RECEPTOR (EXTRINSIC) PATHWAY OF APOPTOSIS

The death receptor or extrinsic apoptotic pathway is initiated upon activation of the TNF death receptors (Fig. 18.2). TNF is the canonical member of the TNF superfamily; additional closely related family members include the TNF-related apoptosis-inducing ligand (TRAIL) and the CD95 ligand (CD95L, also known as FASLG and APO-1L). Upon ligation, signals from the death receptor CD95 (FAS) recruit the adapter FADD and, subsequently, the initiator caspase-8. This brings additional caspase-8 molecules that dimerize and are then activated and cleaved, inducing downstream cleavage of the executioners caspase-3 and caspase-7. This process can be inhibited by c-FLIP, which blocks the dimerization of caspase-8. The protein XIAP, an inhibitor of apoptosis, inhibits the executioner caspases. However, caspase-8 can also cleave the proapoptotic BH3-only protein BID which interferes with antiapoptotic BCL-2 family proteins and activates BAX and BAK, causing MOMP and release of Smac and Omi, which antagonize XIAP, facilitating execution of cell death.

NONAPOPTOTIC FORMS OF CELL DEATH

Necroptosis

Necroptosis (necrosis-like cell death) is a form of caspase-independent programmed cell death that is important in inflammation and viral infection. Necroptosis can be initiated by death receptors, such as FAS and TNFR1,[14–18] TLR3 and TLR4, which recognize pathogens (double-stranded RNA viruses or lipopolysaccharides, respectively), or by the intracellular nucleic acid sensor ZBP1.[19–21] Necroptosis is dependent on the activation of RIPK1 and RIPK3; the latter phosphorylates and activates the effector molecule mixed-lineage kinase domain-like protein (MLKL).[22,23] Phosphorylated MLKL oligomerizes and disrupts the plasma membrane through exposing phospholipids to trigger cell membrane permeabilization and cellular destruction.[24,25] The cell then dies by necroptosis, a process characterized by necrosis-like features, which include cell swelling, membrane disruption, and the release of the intracellular contents.[25,26] Death-receptor triggered necroptosis can only proceed when the caspase-8–c-FLIP complex is inhibited because caspase-8 can cleave RIPK1 and RIPK3, preventing necroptosis. Inhibition of caspases is observed during certain viral infections, in which case necroptosis proceeds as a dominant cell death pathway. Importantly, necroptotic cells release damage-associated molecular patterns (DAMPs) that can induce inflammatory responses.[27] They activate caspase-1, which in turn cleaves proinflammatory interleukin (IL)-1β and IL-18 into mature inflammatory forms. Release of IL-1β is dependent on RIPK3 through caspase-8 or an MLKL-dependent NLRP3 inflammasome. Among the three NLR inflammasomes, NLRP1 and NLRC4 inflammasomes recognize bacterial muramyl dipeptide and flagellins, respectively, while NLRP3 recognizes multiple stimuli, including saturated fatty acids, bacterial RNA, and urate crystals. An inflammatory cell death termed pyroptosis (see below) is initiated by inflammasome activation. Recent findings suggest that dysregulated necroptosis during hematopoiesis promotes bone marrow progenitor cell death that induces inflammation, impairs hematopoietic stem cells, and recapitulates the features of the bone marrow failure disorder myelodysplastic syndrome (MDS).[28] Genetic loss of Ripk1 in hematopoietic cells can be responsible for this bone marrow failure.[29,30] In cancer, necroptosis may facilitate metastasis through damaging endothelial cells.[31]

Ferroptosis

Ferroptosis is an iron-dependent form of regulated necrosis. In ferroptosis, lipid peroxidation occurs in the presence of free iron, which reacts with hydrogen peroxide produced by reactive oxygen species (ROS), a reaction that is further fueled by lipid oxidation in the presence of oxygen and the disruption of cellular membranes. The physiological role of ferroptosis in development and homeostasis remains to be elucidated. Ferroptotic cells exhibit a necrotic-like phenotype, including mitochondrial shrinkage, disrupted cristae, and a ruptured outer mitochondrial membrane, yet these features occur independently of caspase activation or necrosis.[32] Ferroptosis is inhibited by the lipid peroxidase GPX4, which in turn requires glutathione and NADPH for recycling. Accordingly, ferroptosis can be observed under conditions of cysteine/cystine deprivation or inhibition of the cystine/glutamate antiporter Xc^- (i.e., by sorafenib)[33] because these interfere with glutathione synthesis.[34] Reduction in NAPDH or inhibition of GPX4[35] (i.e., by the alkylator altretamine)[36] can also induce ferroptosis. Ferroptosis was first discovered in cancer cells treated with the VDAC2/3 inhibitor erastin,[37] which causes ferroptosis by promoting iron-dependent ROS accumulation. Ferroptosis can be blocked by depletion of free iron (i.e., iron chelation), inhibition of synthesis of polyunsaturated fatty acids, or ROS scavenging using lipophilic antioxidants such as ferrostatin-1. Identification of agents that can selectively induce ferroptosis is actively being pursued in cancer research.[38,39]

Pyroptosis

Pyroptosis is a cell-intrinsic inflammatory form of regulated cell death in response to bacterial, viral, fungal, and protozoan infections. It occurs upon cleavage and oligomerization of the effector molecule gasdermin D (GSDMD), which executes pyroptosis via forming large pores in the membranes. Pyroptosis requires activation of caspases distinct from those involved in apoptosis, including caspase-1 and caspases-4 and -5 in humans and their rodent homolog caspase-11.[40] Caspases-4, -5, and -11 are directly activated by cytosolic lipopolysaccharides from invading gram-negative bacteria and cleave GSDMD in monocytes and other cell types, triggering pyroptosis. In turn, activation of caspase-1 by pathogen-associated pattern recognition receptors like the NLRs and the cytosolic DNA sensor AIM2—or in some instances indirectly through an adapter protein, apoptosis-associated speck-like (ASC) protein—leads to formation of inflammasomes, caspase-1–mediated cleavage of GSDMD, and processing of the cytokines IL-1β and IL-18, which can be released through GSDMD pores.[41] Additional members of the gasdermin family were recently identified as mediators of pyroptosis, one of which, GSDME (also known as DFNA5), is cleaved by caspase-3 that has been activated by TNF or chemotherapy drugs and could be responsible for normal tissue toxicity from chemotherapy.[42] Further characterization of caspase-3 as an activator of GSDME/DFNA5 broadened the role of this type of cell death, which has been recently shown to augment mitochondrial apoptosis.[43]

CELL SURVIVAL AND CELL DEATH PATHWAYS AND ADAPTIVE RESPONSES TO STRESS

Autophagy

Autophagy is defined as "self-eating" and culminates in sequestration of the cytoplasmic material and organelles into a double-membrane structure, the autophagosome, which subsequently is delivered to the lysosome for degradation and recycling.[44] Autophagy permits the cell to maintain homeostasis when faced with metabolic or environmental stressors, including hypoxia, nutrient deprivation, and cytotoxic chemotherapy. In mammals, the core autophagy machinery includes the Atg1-Ulk1 protein complex, which initiates autophagy by recruiting the class III PI3K complex, which is required for recruitment of autophagic factors.[45] The core autophagy proteins, or ATGs, function to generate autophagosomes by encapsulating cytoplasmic cargo within a double-membrane vesicle. These autophagosomes subsequently fuse with acidic lysosomes, and the cytoplasmic material is degraded by pH-sensitive enzymes.[46]

The multistep process of macroautophagy includes phagophore initiation, vesicle nucleation, vesicle elongation, and autophagosome fusion with lysosomes (Fig. 18.3). Phagophores, or isolation membranes, are the precursors of autophagosomes. This pathway is initiated by the Unc-51–like kinase (ULK) complex, which phosphorylates a phosphatidylinositol 3-kinase, VPS34, which is part of the Beclin1 complex required for initiation of the phagophore.[45,47] The ULK complex can be regulated by nutrient availability via mTOR (mammalian target of rapamycin). Vesicle elongation depends on two ubiquitin (Ub)-like conjugation systems. ATG5 is conjugated to ATG12 by the E1-like enzyme ATG7 and the E2-like enzyme ATG10. The ATG5–ATG12 conjugate then binds to ATG16L1, and together they function as an E3-like enzyme (in coordination with ATG7 and ATG3) to facilitate the conjugation of the microtubule-associated LC3 family of proteins to phosphatidylethanolamine (PE). This second conjugation is also aided by ATG7 as well as the E1-like enzyme ATG3. Membrane-associated LC3-PE is incorporated into the autophagosome membrane. SNARE proteins, in conjunction with the small GTPases such as Rab7, facilitate fusion between fully formed autophagosomes and lysosomes. After fusion occurs, the cytoplasmic material within the autolysosome, as well as intravesicular LC3-II, is degraded by pH-sensitive enzymes found within the acidic compartments.

Regulation of autophagy under conditions of nutrient availability occurs primarily through the mammalian target of rapamycin complexes, mTORC1 and mTORC2,[48] as well as 5′ AMP-activated protein kinase (AMPK). Under conditions of amino acid deprivation, mTORC complexes are unable to phosphorylate and inhibit the ULK system, and reduced energy translates into decreased ATP:AMP ratios that induce AMPK, which in turn inhibits mTORC and directly activates the ULK complex.[49] Other cellular stressors, such as hypoxia, endoplasmic reticulum (ER) stress, and metabolic stress, generally regulate autophagy through the above-mentioned key nutrient-sensing pathways. Additionally, the basal autophagy state may be regulated transcriptionally through expression of the core ATGs; examples of transcription factors include TFEB,[50] the forkhead family of transcription factors (FOXO1 and FOXO3),[51] and the epigenetic regulator BRD4.[52]

Tumor cells commonly have high metabolic demands and experience hypoxia and nutrient deficiencies; thus, they use autophagy to promote their survival. For example, under hypoxic conditions, stabilization of hypoxia-inducible factor 1 alpha (HIF1-α) induces activation of proapoptotic proteins that induce autophagy without triggering cell death.[53] Similarly, under nutrient starvation, AMPK activates catabolic autophagy, providing nutrients that sustain tumor cell survival.[49] Certain oncogenes, such as *KRAS*, when mutated, activate autophagy to support primary tumor growth and facilitate metastasis.[54–56] This dependency on autophagy makes it an attractive therapeutic target, and several pharmacological autophagy inhibitors are in clinical development. Further, many cytotoxic agents and some targeted therapies, such as kinase inhibitors, have been shown to induce autophagy as a cytoprotective measure in cancer cells; thus, combinations of these agents with autophagy inhibitors may circumvent therapeutic resistance.[57–59]

Other forms of autophagy include microautophagy (mainly in yeast and plants) and chaperone-mediated autophagy (CMA), which facilitates direct delivery to the lysosome.[60] In CMA, substrates reach the lysosomes through LAMP2A translocation complexes at the lysosomal membrane; these are dismantled by lysosomal HSPA8, and the process does not require vesicles or membrane invagination.[61] CMA is involved in multiple physiological and pathophysiological processes, such as metabolic regulation, aging, neurodegeneration, and T-cell activation, and recently has been implicated in tumorigenesis.[62]

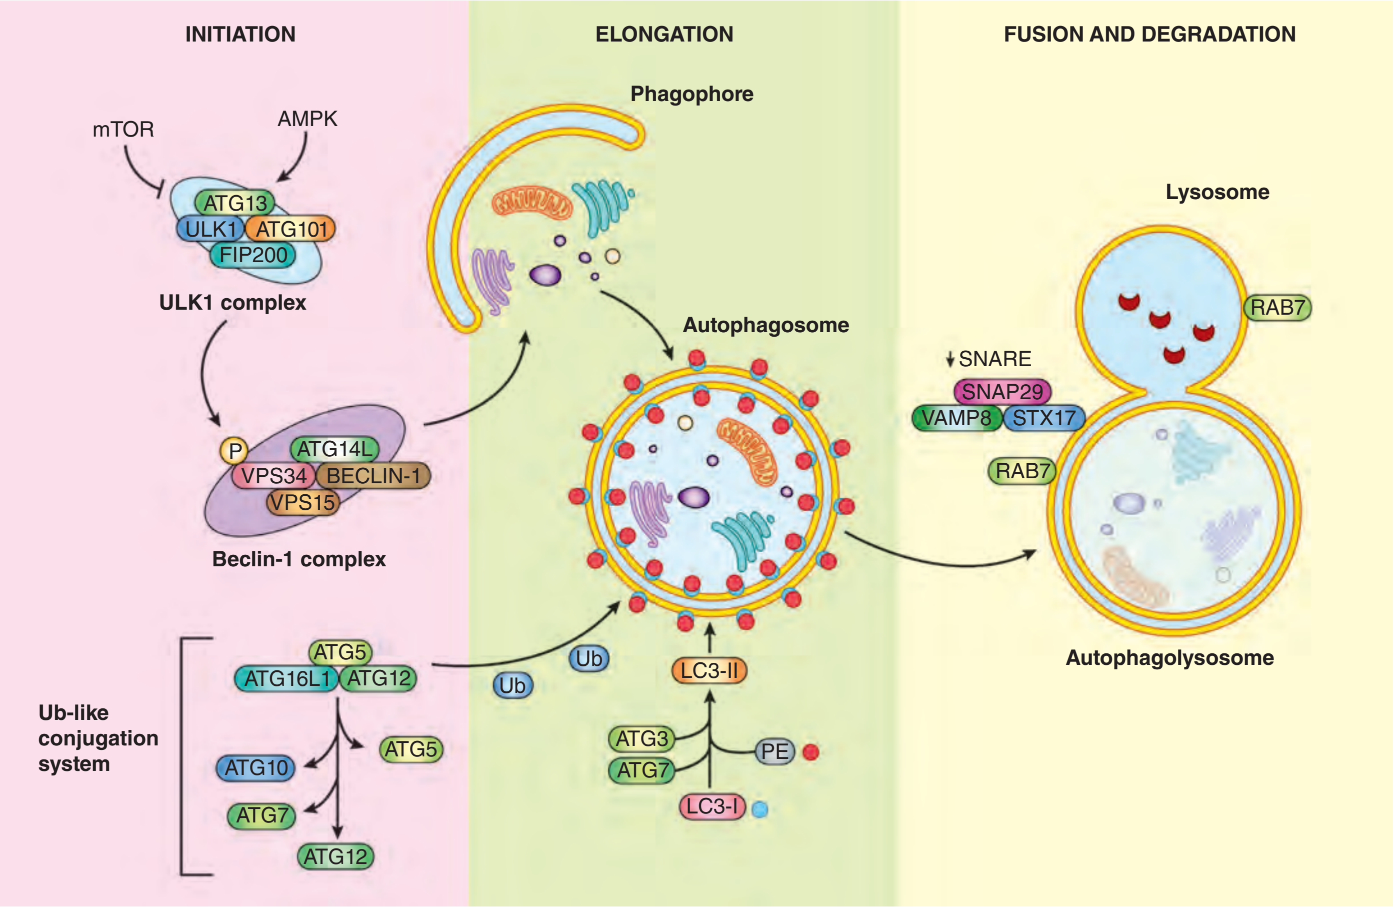

Figure 18.3 AUTOPHAGY SIGNALING.

While in a number of settings autophagy may facilitate cellular demise, this is generally viewed as a failed attempt to support survival. However, autophagic cell death (i.e., a cell death relying on autophagic machinery) has been reported in epithelial cells transformed with *RAS*[63] and in the setting of telomere dysfunction,[64] suggesting that in certain circumstances, autophagy might function to prevent oncogenic transformation.

Unfolded Protein Response

Protein stress responses that engage the unfolded protein response (UPR) during ER-induced stress may antagonize cell death or eventually lead to apoptosis. In the ER, over a third of all cellular proteins undergo processing, including protein folding, posttranslational manipulations, and structural maturation. Despite the robustness of the ER machinery, cells often function at the limit of their secretory capacity, and a wide variety of conditions can disrupt protein folding and result in the accumulation of misfolded proteins, known as ER stress. These triggers include nutrient deprivation, hypoxia, ROS accumulation, and loss of calcium homeostasis. The UPR engages three key signaling stressors located in the ER: PKR-like ER kinase (PERK), IRE1 (α and β), and activating transcription factor-6 (ATF6, α and β). These pathways regulate transcription of genes involved in resolving ER stress but also induce transcription of genes involved in apoptosis, causing the death of cells that are unable to manage the stress. Activation of PERK through autophosphorylation inhibits protein translation through the phosphorylation of eukaryotic translation initiator factor-2 (eIF2α) at serine 51, which also represents a convergence point for the so-called integrated stress response. eIF2α phosphorylation reduces the overall protein load but simultaneously induces mRNA translation of the transcription factor ATF4, which increases the antioxidant response and ER folding capacity and may also trigger macroautophagy. ATF4 also regulates the expression of genes involved in apoptosis, including the transcription factors TP53, C/EBP-homologous protein (CHOP), and growth arrest and DNA damage-inducible 34 (GADD34). CHOP inhibits expression of the antiapoptotic BCL2 and induces that of proapoptotic proteins such as BIM and NOXA. IRE1α is a transmembrane protein that, in response to unfolded proteins, catalyzes splicing of the XBP1 transcription factor, which in turn regulates transcription of genes involved in protein folding, secretion, and translocation. The second functional output of IRE1α is degradation of multiple mRNAs, microRNAs, and rRNAs in the cytosol and ER through a process called regulated IRE1-dependent decay, or RIDD, which is mediated by the RNase cytosolic domain of IRE1α. The RIDD function of IRE1α degrades specific microRNAs that affect the translation of caspase-2 to induce apoptosis via BID.[65] ATF6α is also an ER transmembrane protein that, under ER stress, undergoes cleavage and releases its cytosolic domain-containing transcription factor, ATF6f, which causes transcription of genes that regulate ER-associated degradation of unfolded proteins.

Emerging evidence from multiple experimental systems indicates that select protein modulators of UPR can promote either cell survival or cell death, depending on the extent of ER damage or the duration of UPR. Recent data indicate the important role of UPR in the regulation of the cancer-associated processes of metastasis, angiogenesis, and chemoresistance.[66] Although it remains to be determined whether agents targeting UPR regulators could be used as cancer therapeutics, recent studies have reported preclinical efficacy of small molecules that inhibit PERK or IRE1a in cancer models.[67]

CLINICAL APPLICATIONS

Given the central role of the BCL2 superfamily in the pathogenesis of cancer and in the mechanisms of chemoresistance, BCL2 targeting has in recent years been a highly sought-after therapeutic strategy in oncology, and its most successful application has taken place in the field of hematological malignancies.

PRECLINICAL ACTIVITY OF BCL2 ANTISENSE AND BH3-MIMETICS IN MYELOID MALIGNANCIES

Four BCL2-targeting agents have shown significant pre-clinical activity for the treatment of myeloid malignancies. These include a BCL2 antisense (oblimersen) and 4 BH3-mimetics (obatoclax, navitoclax, ABT-737, and venetoclax).

Preclinical Activity of Oblimersen in Acute Myeloid Leukemia

Oblimersen, formerly G3139, is a synthetic single-stranded phosphorothioate DNA oligonucleotide that downregulates BCL2 mRNA expression by selective hybridization. Formation of the RNA/antisense DNA duplex recruits RNase H, which degrades the RNA strand and prevents translation of the BCL2 protein.[68] In serum-free cultures of CD34+ normal marrow cells, BCL2+ myeloid cell lines, and acute myeloid leukemia (AML) cells, oblimersen treatment reduced BCL2 protein expression, decreased cell survival, and reduced the number of clonogenic cells. When oblimersen was used in combination with chemotherapeutic drugs, a synergistic killing effect was observed in AML cells.[69] While antisense mRNA compounds appear to be effective, subsequent preclinical efforts have been aimed at developing small-molecule BH3-mimetics that can occupy the BH3 binding grove of BCL2 and other antiapoptotic proteins and inhibit their activity.

Preclinical Activity of Obatoclax in Acute Myeloid Leukemia

Obatoclax, formerly called GX15-070, is a polypyrrole identified from a screen of natural compounds. It nonselectively inhibits BCL2 and multiple BCL2 alternative proteins, including BCL-XL, BCL-W, BCL2-A1, and MCL-1. It induces release not only of cytochrome C from mitochondria, but also of BAK from MCL-1 and BIM from both BCL2 and MCL-1, thereby inducing the formation of an active BAK:BAX complex, crucial effector proteins within the intrinsic apoptosis pathway. In preclinical studies, obatoclax inhibited growth of multiple AML cell lines and induced apoptosis in primary AML samples. In addition, it showed synergistic activity with chemotherapeutic agents and other BH3-mimetics such as ABT-737 (see below).[70]

Preclinical Activity of Navitoclax and ABT-737 in Acute Myeloid Leukemia

Navitoclax, formerly ABT-263, is a synthetic small-molecule BH3-mimetic that selectively inhibits BCL2, BCL-XL, and BCL-W, whose pre-clinical activity has been mostly observed in ALL models. It was derived by modification in three molecular positions of the first-generation, highly potent, synthetic small molecule BH3-mimetic ABT-737 to allow higher solubility, better oral bioavailability, and therapeutic use. In preclinical testing, ABT-737 induced the disruption of the BCL2:BAX complex and BAK-dependent but BIM-independent activation of the intrinsic apoptotic pathway, resulting in effective killing of AML blast, progenitor, and stem cells without affecting normal hematopoietic cells.[71] Unexpectedly, ABT-737 also induced activation of the extracellular receptor activated kinase (MAPK ERK) and of MCL-1 in AML cells, and its combination with MEK inhibitors resulted in potent synergistic killing of AML-derived cell lines, primary AML blasts, and CD34+CD38-CD123+ progenitor/stem cells.[72] A potent synergistic effect in inducing killing of primary AML and MDS cells was observed when ABT-737 was used in combination with hypomethylating agents (likely because of MCL-1 decrease) and FLT3 inhibitors.[73,74]

Preclinical Activity of Single-Agent Venetoclax in Acute Myeloid Leukemia

Venetoclax, formerly ABT-199, is a BH3-mimetic that is highly selective for BCL2.[75] Unlike previously investigated BH3-mimetics, venetoclax does not affect BCL-XL, on which platelet precursors are highly dependent.[70,71,76] This molecular feature has been critical for the subsequent clinical development of venetoclax for the treatment of AML, a disease typically associated with thrombocytopenia.[75]

In the first preclinical study of venetoclax in AML,[77] AML cell lines were similarly sensitive to venetoclax or the dual Bcl-2/XL inhibitor ABT-263. However, in BCL2-sensitive cell lines (such as MOLM-13), venetoclax more effectively induced cell killing, likely because of its five-fold higher affinity for BCL2.[75] These findings were confirmed in vivo in an aggressive mouse xenograft model of MOLM-13; venetoclax treatment significantly inhibited AML progression and extended mouse survival. Finally, ex vivo studies showed that both AML myeloblasts and AML stem/progenitor cells derived from patients' blood or bone marrow were highly sensitive to venetoclax, except for cases with complex karyotypes and *JAK2* mutations.

Combination Strategies to Boost Venetoclax Activity and Overcome Venetoclax Resistance

BH3 profiling has shown a consistent positive correlation between venetoclax sensitivity and BCL2 dependence and a negative correlation with MCL-1 dependence. Thus, studies have investigated combination strategies to overcome venetoclax resistance (Table 18.2).[77]

Combinations of daunorubicin or cytarabine with venetoclax have been investigated, both in AML cell lines and patient-derived samples.[78] These combinations reduced MCL-1 protein levels (which was instead increased by the use of single-agent venetoclax), resulting in synergistic apoptosis of AML cells. Synergistic activity was also reported for venetoclax and less-intensive chemotherapy agents, such as hypomethylating agents and histone deacetylase inhibitors. For instance, the use of venetoclax sensitized both AML cell lines and patient-derived AML samples to subsequent use of the hypomethylating agent azacitidine.[73,79] Interestingly, in vitro, agents such as navitoclax that can inhibit multiple BCL-2 family members exerted a stronger synergy than venetoclax in AML cell lines, but their potency was similar to that of venetoclax in ex vivo drug dose combination response assays in primary AML and MDS/chronic myelomonocytic leukemia samples.[73,80] This discrepancy was explained by the greater dependency of the AML-derived cell line panel on BCL-XL and/or BCL-W than of the primary samples analyzed ex vivo, as confirmed by BH3 profiling.[80] Importantly, it was recently observed that LSCs in de novo AML rely on amino acid metabolism for oxidative phosphorylation and survival.[11] Venetoclax plus azacitidine induced LSC toxicity in vitro by decreasing amino acid uptake, as confirmed by decreased α-ketoglutarate and increased succinate levels. These findings suggest that the combination of venetoclax and azacitidine inhibits its electron transport chain complex II, which was observed in LSCs derived from AML patients treated with this combination on a clinical trial.[81] The potential for this combination to eliminate LSCs is further supported by the fact that in a cohort of AML patients who were not eligible for intensive chemotherapy but were treated with venetoclax in combination with azacitidine or decitabine, 45% of those achieving complete remission also experienced eradication of minimal residual disease, with less than 10^{-3} leukemic cells observed in bone marrow samples at the time of response assessment.[82]

Moreover, in both AML cell lines and primary patient samples, the combination of venetoclax and the histone deacetylase inhibitor panobinostat synergistically induced apoptosis by upregulating BIM, and short hairpin RNA–mediated knockdown of BIM in AML cell

TABLE 18.2 Agents With Preclinical Evidence of Synergy With Venetoclax in Acute Myeloid Leukemia Models

Drug Name	Drug Class
Chemotherapy Agents	
Daunorubicin	Anthracycline
Cytarabine	Nucleoside analogue
Epigenetic Regulators	
Azacitidine	Hypomethylating agent
Panobinostat	Histone deacetylase inhibitor
Targeted Agents	
Alvocidib (flavopiridol)	CDK9 inhibitor
A-1592668	CDK9 inhibitor
MLN4924 (pevonedistat)	NED inhibitor
GDC-0980	PI3K/mTOR inhibitor
RG7388 (idasanutlin)	MDM2 antagonist
GDC-0973 (cobimetinib)	MEK inhibitor
A-1210477	MCL-1 inhibitor
VU661013	MCL-1 inhibitor
AMG 176	MCL-1 inhibitor
Quizartinib	FLT3 inhibitor
Enasidenib	IDH2 inhibitor

lines abrogated the benefit of the addition of panobinostat. These findings highlight the role of BIM as a potential target for overcoming MCL-1–mediated venetoclax resistance in AML.[83]

Multiple targeted agents that can directly or indirectly affect MCL-1 function have been investigated in combination with venetoclax in AML models. The cyclin-dependent kinases (CDKs) are a group of serine-threonine kinases; CDK9 regulates the transcription of prominent oncogenes, including *MYC* and *MCL1*. Alvocidib (also known as flavopiridol), a potent CDK9 inhibitor, has been shown to downregulate MCL-1 expression and increase BIM expression, thereby inducing synergistic apoptosis when combined with venetoclax in venetoclax-resistant AML cell lines (such as OCI-AML3), patient-derived samples, and a mouse xenograft model of OCI-AML3.[84] Similarly, A-1592668, an orally active CDK9 inhibitor, effectively downregulates RNA polymerase II phosphorylation at serine 2, resulting in the loss of MCL-1 protein expression; it synergistically induced cell death when combined with venetoclax in multiple myeloid cell lines and an AML mouse model.[85]

MLN4924 (also known as pevonedistat), an inhibitor of the Nedd8 activating enzyme NAE, has been demonstrated to inactivate E3 Cullin ring ligases (CRLs), causing accumulation of the CRL substrate c-Myc, which transactivates the *PMAIP1* gene (encoding NOXA), thus inducing upregulation of NOXA and subsequent MCL-1 inhibition. This synergistically led to apoptosis when MLN4924 was combined with venetoclax, both in cell lines and primary patient samples.[86] GDC-0980, a PI3K/mTOR inhibitor, has been shown to induce MCL-1 downregulation and BAX activation, resulting in marked apoptosis in venetoclax-resistant AML cell lines, patient-derived myeloblasts, and both cell line-derived and patient-derived xenograft mouse models of venetoclax-resistant AML.[87]

RG7388 (also known as idasanutlin), an MDM2 antagonist, activates p53, which negatively regulates the Ras/Raf/MEK/ERK pathway and activates GSK3 to modulate MCL-1 phosphorylation and promote its degradation.[88,89] In addition, p53 induces its downstream proapoptotic targets BAX and NOXA. When RG7388 was combined with venetoclax, it synergistically induced apoptosis in p53-intact AML cell lines and xenograft mouse models of venetoclax-resistant AML.[88 89]

The combination of GDC-0973 (also known as cobimetinib), a direct MEK inhibitor, with venetoclax was shown to specifically target leukemia progenitors that express high levels of BCL2 and to suppress the cytokine-induced pERK and pS6 signaling pathways. This combination also downregulated MCL-1 and disrupted both the BCL2:BIM and MCL1:BIM complexes, with the most marked effects in cell lines enriched with pathways including MYC, mTORC1, and p53. This produced significant growth-inhibitory activity both in AML cell lines (including those resistant to single agents) and patient-derived samples (including those with multiple genetic aberrations) and translated into significant reduction of the leukemia burden in xenograft OCI-AML3 and MOLM13 models.[90]

Finally, multiple direct MCL-1 inhibitors have been investigated in combination with venetoclax in preclinical models of AML, including A-1210477, VU661013, and AMG176. The activity of A-1210477 has been investigated both alone and in combination with venetoclax, with the combination showing synergistic induction of apoptosis both in AML cell lines and in patient-derived samples owing to decreased MCL-1–mediated sequestration of BIM.[91] VU661013 has been shown to destabilize the association between BIM and MCL-1, leading to apoptosis in venetoclax-resistant AML cells and patient-derived xenografts; the combination of VU661013 and venetoclax also showed significant activity in murine models of AML.[92] Similarly, AMG176 had synergistic effects when combined with venetoclax in AML tumor models and primary patient samples.[93]

Novel Venetoclax-Based Combinations

Multiple studies in recent years have investigated the efficacy of the combination of venetoclax with novel agents approved and clinically available for the treatment of patients with AML, such as FLT3 inhibitors and IDH1/2 inhibitors. The efficacy of quizartinib, an FLT3 inhibitor, in combination with venetoclax was investigated in a *FLT3*-mutated xenograft mouse model; the use of the combination resulted in more durable responses than did monotherapy.[94] Interestingly, the same study investigated the combination of venetoclax with BCL2, BCL-XL, and MCL-1 inhibitors in *FLT3*-ITD+ cells in vivo and found synergy between quizartinib and venetoclax but not between quizartinib and BCL-XL or MCL-1 inhibitors. It is important to note that earlier studies showed that *FLT3*-ITD or *PTPN11* mutations enhanced the expression of other members of the BCL-2 family, including BCL-XL and MCL-1, providing a potential explanation for venetoclax resistance in these contexts, which has been confirmed in a clinical setting.[95–97]

In a large-scale RNA interference screen aimed at identifying genes that were synthetically lethal with *IDH1/2* mutations in AML, *IDH1/2*-mutant primary human AML cells were more sensitive to venetoclax than were *IDH1/2* wild-type cells, both ex vivo and in xenograft mouse models.[98] Similar findings were reported for a chemical screen of about 300 drugs in a cohort of 38 primary human AML specimens.[99] By producing R-2-hydroxyglutarate, *IDH1/2*-mutant cells inhibit the activity of cytochrome c oxidase in the mitochondrial electron transport chain, lowering the mitochondrial threshold at which apoptosis is triggered upon engagement with venetoclax. Based on these findings, the combination of venetoclax with enasidenib, an oral IDH2 inhibitor, was investigated in three patient-derived xenograft models of human *IDH2*-mutant AML; the results showed that the combination reduced leukemia engraftment more effectively than did single-agent therapy.[100,101]

CLINICAL DEVELOPMENT OF BH3-MIMETICS FOR MYELOID MALIGNANCIES

Clinical Development of Oblimersen for Acute Myeloid Leukemia

The safety and efficacy of oblimersen was initially investigated in combination with FLAG (fludarabine, cytarabine, and granulocyte colony-stimulating factor) in a phase I study including 17 patients with refractory or relapsed AML.[102] Seven patients had a response, and no dose-limiting toxicity was observed, leading to a subsequent phase I trial of the combination of oblimersen, cytarabine, and daunorubicin in 29 patients with previously untreated AML.[103] Fourteen patients experienced remission, 7 of whom later had disease relapse, and no significant toxicity was observed. Of interest, after a 72-hour infusion of this combination, *BCL2* mRNA copies were significantly decreased from baseline in patients who went on to have remission. A phase II study further explored the efficacy of oblimersen in combination with gemtuzumab ozogamicin in older patients with AML at time of first relapse. This study showed a remission rate of 25% and durable responses.[104] Despite its clinical activity and limited toxicity, the clinical development of oblimersen has not moved forward, mainly because it requires weekly continuous infusions.

Clinical Development of Obatoclax for Acute Myeloid Leukemia

The safety and efficacy of single-agent obatoclax was initially investigated in a phase I study including 25 patients with relapsed AML and/or patients with previously untreated disease who were ineligible for induction chemotherapy.[105] A response was observed in only 1 patient, and most of the participants experienced transient neurological complications after the infusion. A subsequent phase II study investigated the activity of single-agent obatoclax in 24 patients with previously untreated MDS, but the study was stopped early because of limited efficacy.[106]

Clinical Development of Venetoclax for Acute Myeloid Leukemia

Single-agent venetoclax was initially investigated in a phase II study including 58 patients with relapsed or refractory AML. It showed limited efficacy, with an overall response rate of 19%, and a short median response duration of 48 days.[107] Notably, 4 of 12 patients with *IDH1/2* mutations had a complete response. This led to the further development of biologically rationally designed combination strategies. The combination of venetoclax and azacitidine or decitabine was investigated in a phase Ib study including 145 elderly patients with previously untreated AML. Thrombocytopenia, neutropenia, and febrile neutropenia were the most common grade 3 or higher adverse events; the complete response rate was 77% and median overall survival was 18 months.[108] The combination of venetoclax and low-dose cytarabine was investigated in a phase I/II study including older patients with previously untreated AML. This combination showed a similar toxicity profile to venetoclax and azacitidine, and among the 82% of patients who received the maximum tolerated dose of venetoclax, the complete response rate was 54% and median overall survival was 10 months.[109] Based on these data, in 2018 the FDA approved the combination of venetoclax and azacitidine or decitabine or low-dose cytarabine for the initial treatment of AML in adults 75 years of age or older or who have comorbidities that preclude the use of intensive induction chemotherapy. A confirmatory phase III randomized trial has been recently published, with results further supporting use of this combination.[110] In that study, 431 patients with previously untreated AML who were ineligible for standard chemotherapy were randomized to receive azacitidine alone or in combination with venetoclax. After a median follow-up of 21 months, patients treated with the combination had a significantly higher complete remission rate (37% vs 18%) and longer median overall survival (15 months vs 10 months), in spite of a higher rate of febrile neutropenia.

A list of published venetoclax-based combination studies is shown in Table 18.3. Multiple novel studies based on the above-outlined preclinical data are ongoing. These studies involve chemotherapy backbones, targeted agents, and immune oncology agents and may significantly improve the outcomes of patients affected by AML and other myeloid malignancies.

A deep understanding of apoptosis, a hallmark of cancer, has translated into the development of novel and effective biological agents for the treatment of hematological malignancies; a deeper knowledge of

its interactions with other biological pathways is now contributing to the development of safer and more effective therapeutic strategies.

RATIONALE FOR USE OF BH-3 MIMETICS IN CHRONIC LYMPHOCYTIC LEUKEMIA

The majority of patients with chronic lymphocytic leukemia (CLL) harbor deletion of a portion of the long arm of chromosome 13 [del(13q)]. Two important microRNA (miR) genes, miR15 and miR16, were identified in the critical minimal deleted region of del(13q) and were noted to be deleted or down-regulated in more than two-thirds of all CLL cases.[111] MicroRNAs are non-translated small RNAs that function to regulate gene expression. Both miR15 and miR16 down-regulate *BCL-2* transcript levels. The absence of miR15 and miR16 in cases with del(13q) leads to increased BCL-2 expression[112] and resultant resistance to apoptosis.

In vitro treatment of CLL cells with navitoclax (ABT-263), the small molecule inhibitor of BCL-2, BCL-w, and BCL-xL, potently induced cell death. A phase I/II trial of orally administered navitoclax was conducted and generated promising results. The majority of patients treated in the study had greater than 50% reduction in leukemia counts and some patients experienced reduction in lymph node size.[113] The dose limiting toxicity was thrombocytopenia secondary to accelerated platelet senescence from inhibition of BCL-xL in platelets. Given this activity, venetoclax (ABT-199) was designed as a molecule with greater affinity for BCL-2 and reduced affinity for BCL-xL.[75]

This mechanism of action is independent of p53, making it particularly appealing for high-risk patients who lack *TP53*, such as those with del(17p) and patients who have mutated *TP53*.

CLINICAL DEVELOPMENT OF VENETOCLAX FOR CHRONIC LYMPHOCYTIC LEUKEMIA

Venetoclax is approved for treatment of patients with CLL, both as monotherapy and combined with CD20 antibody, developed through a series of phase I–III trials (Table 18.4). Venetoclax was initially studied in a phase I clinical trial that included patients with CLL as well as other lymphoid malignancies.[114,115] This trial identified tumor lysis syndrome (TLS) as a significant risk but did not identify a maximum tolerated dose or dose-limiting toxicity. The occurrence of clinical TLS was mitigated through a weekly ramp-up schedule for initiating venetoclax. The effective dose identified for CLL in this trial was 400 mg daily.

The pivotal trial that led to initial approval for venetoclax as continuous monotherapy was a phase II trial for relapsed or refractory del(17p) CLL(M13-982, see Table 18.4).[116] This trial demonstrated responses, including complete remissions, and undetectable MRD at 10^{-4} sensitivity (uMRD4) demonstrating the deepest remission, in a population of heavily previously treated patients with del(17p) CLL. Responses were durable; an estimated median progression-free survival (PFS) of 24 months was reported in this population.

Continuous monotherapy was also investigated in patients who were refractory or intolerant to B-cell receptor signaling pathway inhibitors, including ibrutinib and idelalisib (M14-032).[117,118] Responses were noted in both subgroups and were durable.

Venetoclax was initially combined with the CD20 antibody, rituximab, in a phase Ib trial exploring tolerability of this combination for relapsed and refractory patients with CLL (M13-365).[119] In addition, venetoclax was studied with obinutuzumab in another phase Ib trial that enrolled both first-line and relapsed CLL.[120] This trial evaluated schedules of treatment initiated first with obinutuzumab then venetoclax ramp-up and vice versa, and showed both schedules were safe. Similarly, the phase III CLL14 trial studied cycle 1 with obinutuzumab initiated alone; venetoclax ramp-up was initiated on day 22 of cycle 1.[121] Cycle 1 obinutuzumab single-agent was highly effective at reducing lymphocytosis prior to initiating venetoclax in these studies.

Larger randomized phase III clinical trials demonstrated improved PFS with venetoclax-based therapy over chemoimmunotherapy (see Table 18.4).[121–124] The MURANO trial evaluated venetoclax plus rituximab for patients with previously treated CLL.[122,123] The control arm received the standard 6 cycles bendamustine plus rituximab. The CLL14 trial evaluated venetoclax plus obinutuzumab in treatment naïve CLL and compared to treatment with chlorambucil plus obinutuzumab.[121] These trials showed remarkably improved outcomes and depth of remission associated with venetoclax-based therapy over chemoimmunotherapy.

In vitro studies demonstrated reduced MCL1 with BTKi treatment potentially making cells more vulnerable to BCL2i-induced apoptosis.[125] Combined targeted therapy with BTKi and BCL2i was evaluated in three early, phase I/II clinical trials.[126–128] Data were initially available for the MD Anderson[127] and CLARITY[126] studies, which clearly demonstrated high uMRD4 rate in both first-line and relapsed CLL. The CAPTIVATE study investigated 12 cycles of combined ibrutinib and venetoclax followed by randomization based on confirmed uMRD4 status.[128] Patients who were confirmed undetectable were randomized to continued ibrutinib single-agent versus placebo and those unconfirmed for uMRD4 were randomized to continued ibrutinib single-agent versus continued combined therapy. The post-randomized, 1-year disease-free survival rate was similar between those patients assigned to placebo versus continued ibrutinib. None of the three trials identified safety or tolerability concerns with this combination.

Venetoclax was also combined with BTKi (ibrutinib[129] or acalabrutinib,[130] a second-generation BTKi) and obinutuzumab (see Table 18.4). These trials showed similar tolerability and safety with these combinations.

MECHANISMS OF RESISTANCE TO VENETOCLAX IN CHRONIC LYMPHOCYTIC LEUKEMIA

Several mechanisms of acquired clinical resistance to venetoclax-based treatment have been described. These include increased expression of other anti-apoptotic BCL-2 family proteins, such as Mcl-1 and BCL-xL, which raise the threshold of apoptosis and decrease cell dependence on BCL-2.[131] One potential mechanism for increasing BCL-xL levels is through reduction in miR-377.[132] Furthermore, mutations that block venetoclax binding of BCL-2 have been described in clinical samples from patients who develop clinical resistance, including: G101V,[133] D103Y,[134] and F104I.[134] Finally, metabolic changes can also alter dependence and response to BH3-mimetics and regulate BCL-2 levels.

SUMMARY

Apoptosis, or programmed cell death, is an evolutionarily conserved, highly regulated mechanism for maintaining cell and tissue homeostasis in multicellular organisms. Physiological apoptotic process may proceed through an intrinsic, mitochondria-dependent pathway, or an extrinsic pathway that depends on the death signal and cell type involved. The BCL-2 family of proteins is situated upstream of irreversible cell damage in the apoptotic pathway, providing a pivotal checkpoint in the fate of a cell after a death stimulus. BH3-only BCL-2 members connect distinct upstream signal transduction pathways with the common, core apoptotic pathway. Cancer cells hijack this apoptotic machinery and utilize it to facilitate their survival. Understanding the molecular mechanisms of cell death and the critical dependencies of specific cancers has led to the discovery of several BH3-mimetics that are currently approved or are undergoing clinical trials for use in targeted cancer therapy.

CHAPTER

19

AGING AND HEMATOPOIESIS

Daozheng Yang, Arthur Flohr Svendsen, and Gerald de Haan

AGING

Increase in life expectancy has resulted in a major demographic global shift toward an elderly population. As a consequence, the prevalence of a multitude of age-associated diseases has increased gradually during the last decades, resulting in an increased number of hospitalizations of elderly individuals. A better understanding of the mechanisms that cause aging is crucial in order to mitigate age-associated clinical conditions.

Multiple "hallmarks" of cellular/molecular aging have been proposed.[1] Aging is a heterogeneous process, leading to impairment, malfunction, and failure of cells and tissues. One of the hallmarks of aging relates to stem cell exhaustion. Tissue homeostasis is maintained by stem cells, and their regenerative potential is severely reduced during normal aging. The hematopoietic system is affected by this process in different ways. In this chapter, we focus on the clinical hematological manifestations that are observed in elderly individuals and discuss the potential molecular causes of age-associated dysfunctions.

HEMATOPOIETIC STEM CELL POTENTIAL DECLINES WITH AGING

Hematopoietic stem cells (HSCs) are a rare population of bone marrow (BM) cells that harbor the potential to replenish every mature blood cell, thus maintaining hematopoietic homeostasis. HSCs are also able to self-renew—upon cell division, at least one of the daughter cells maintains stem cell properties—in order to maintain the stem cell pool throughout the lifespan. Yet, a wide variety of studies have documented numerous hematological changes in elderly individuals, suggesting that HSCs lose their full potential during the lifespan of an individual.

Quantitatively, there is an increase in the absolute number of phenotypical HSCs, while elderly individuals show a decreased number of more mature hematopoietic cells. The increased number of HSCs seems to be a compensatory mechanism in order to maintain blood production and also indicates that aged HSCs have a diminished functional capacity.[2] Indeed, allogenic BM transplantation studies demonstrated that HSCs derived from aged donors have diminished engraftment potential and reduced self-renewal capacity compared to HSCs from younger donors.[3]

Another characteristic of aged HSCs is their skewed differentiation potential, where differentiation toward myeloid progenitors is favored over differentiation to red blood cells (RBCs) and lymphocytes.[2,3] This myeloid skewing has profound implications for age-associated clinical manifestations, and it has been under intense investigation. We cover both aspects in the following sections. First, we describe the most common hematological age-associated clinical manifestations.

CLINICAL MANIFESTATIONS

Anemia

By far the most prevalent age-associated hematological condition is anemia. Studies demonstrated that 10% to 24% of elderly individuals develop some form of anemia, where idiopathic cytopenia of unknown significance with isolate anemia (ICUS-A), commonly known as "anemia at older age" is the most prevailing.[4] According to the World Health Organization (WHO), anemia in older individuals occurs when hemoglobin (Hb) levels are less than 13 g/dL in men and less than 12 g/dL in women.[4] Multiple epidemiological studies have associated low Hb levels as risk factors for cardiovascular diseases, cognitive impairment, and insomnia. Furthermore, anemia has been associated with diminished physical performance and more frequent and longer hospitalizations among elderly patients.[4]

The development of anemia at an older age is multifactorial. Malnutrition is the cause of the majority of cases, where deficiency of primarily iron but also folic acid and vitamin B12 hampers RBC production. Specifically in elderly patients, gastrointestinal (GI) tract problems, polypharmacy, and even social isolation have been reported to be significant contributors.[4] Chronic inflammation can also cause anemia, with as many as one-third of patients older than 65 years old displaying a chronic inflammatory state. Common age-related chronic diseases such as chronic kidney disease, rheumatoid arthritis, and different kinds of neoplasms affect systemic inflammatory cytokine levels. These inflammatory cytokines negatively affect erythroid precursors cells in the BM. In addition, erythropoietin (EPO)—the main regulator of erythropoiesis—is usually reduced, leading to decreased RBCs production.[4]

Immunosenescence

Elderly patients often display immunosenescence, which is defined by a reduced ability to combat new pathogens, the accumulation of memory T cells, and a chronic and systemic state of inflammation, termed "inflammaging" (see the discussion in the following sections).[5] One of the proposed causes of a hampered immune response in elderly individuals is the myeloid skewing of aged HSCs. Since myeloid differentiation is favored, the B and T cell population diversity is diminished and the adaptive immune response is impaired. The lack of an adequate immune response in conjunction with a chronic inflammatory state has profound implications and contributes to age-associated clinical manifestations such as susceptibility to infections, diverse types of cancer, autoimmune and neurodegenerative diseases, and atherosclerosis.[3]

Myelodysplastic Syndromes

Elderly individuals may display changes in hematopoiesis which are closely related to bone marrow failure (BMF) syndromes. The most prevalent of these, myelodysplastic syndrome (MDS), is composed of a heterogeneous group of clonal myeloid disorders. This syndrome is characterized by ineffective hematopoiesis, cytopenias—often severe anemia (<10 g/dL)—and dysmyelopoiesis. During normal aging, hematopoiesis displays similar changes as seen in MDS patients, and these pathological findings are associated with an increased risk for transformation into acute myeloid leukemia (AML).[3,6] Overall, phenotypes associated with normal aging and pathological BMF are generally caused by loss of HSC function, which in turn results in aberrant blood cell formation.[3]

Currently, there are a restricted set of approved drugs for MDS treatment, and none are curative. HSC transplantation is potentially the only curative intervention, but there are significant limitations in terms of donor/recipient compatibility and recipient age-associated comorbidities.[6]

The pathogenesis of MDS has been well studied and specific molecular mechanisms have been identified. Somatic mutations are consistently found in MDS patients and are associated with different prognoses. Mutations in genes such as *ASXL1*, *EZH2*, *RUNX1*, *SRSF2*, and *TP53* are associated with poor prognosis. Interestingly, some of these genes are also mutated in elderly patients with no clinical manifestations (see the clonal hematopoiesis section). Moreover, the acquisition of somatic mutations in non-hematopoietic cells in the BM microenvironment has been shown to also contribute to niche remodeling, favoring neoplastic hematopoietic progenitors that eventually can initiate disorders such as MDS and AML.[3,6]

Leukemia

There is a strongly increased incidence of many types of cancer across different tissues in elderly patients, including age-associated hematological malignancies. These malignancies are generally believed to be caused by time and the proliferation-dependent accumulation of somatic mutations.[3]

Specifically, in aged individuals, there is a high prevalence of and mortality from AML and chronic lymphoid leukemia (CLL) (Fig. 19.1). Although both types of malignancies are strongly age-dependent, they show distinct development, onset, and result from very distinct mutations.[7] Whereas CLL is considered to emerge from mature and differentiated lymphocytes, AML arises from undifferentiated hematopoietic stem and progenitor (HSPC) populations.

CLONAL HEMATOPOIESIS, CLONAL HEMATOPOIESIS OF INDETERMINATE POTENTIAL, AND AGE-RELATED CLONAL HEMATOPOIESIS

In the 1960s, it was established that X chromosomal inactivation (XCI) is a random process that takes place at the early female embryonic developmental stages. Since the same X chromosome remains inactive upon multiple cell divisions, XCI analysis allows for low-resolution clonal tracking. As hematological malignancies arise from single clones, clonal tracking is a powerful tool that allows for disease monitoring and understanding.[8]

Only recently, high-resolution clonality analyses of healthy individuals without malignant transformation demonstrated two remarkable features. First, mature blood cells from these individuals showed imbalanced clonality, suggesting that some HSC clones produced more mature blood cells than others, resulting in their progeny being overrepresented. This is referred to as (oligo-) clonal hematopoiesis. Second, when assessing the presence of clonal hematopoiesis in different age groups, 0.5% of individuals younger than 50 years old, 2% to 3% in elderly individuals, and a remarkable 10% to 20% of elderly individuals above 70 years old showed clonal hematopoiesis.[8–10] Thus, clonal hematopoiesis does not only occur during normal hematopoiesis but also is strongly correlated with age.

Insight in clonal hematopoiesis and its relationship with leukemia emerged when driver mutations were assessed in individuals with normal clonal hematopoiesis. *TET2* mutations were detected in 5% of older individuals with clonal hematopoiesis, but such mutations were not detected in individuals with non-clonal hematopoiesis. This was the first time that a mutation associated with myeloid leukemia was found to be present and compatible with normal hematopoiesis, corroborating the idea that leukemia arises from the acquisition of sequential mutations and that clonal hematopoiesis acts as a pre-leukemic state.[2,8–10]

With advancements in DNA exome sequencing, studies have revealed the mutation profile of large cohorts of individuals within different age categories and inclusion criteria (presence of hematological neoplasia, psychiatric and cardiovascular disorders). Individuals with clonal hematopoiesis showed a restricted pattern of mutations in genes involved in different cellular processes. However, the most striking mutation profile, found in more than two-thirds of these individuals, affected the coding sequence of a small number of epigenetic genes, particularly *DNMT3A*, *TET2*, and *ASXL1*.[2,8–10]

It may be relevant to distinguish between various types of clonal hematopoiesis. First, individuals with clonal hematopoiesis do not necessarily carry mutations in driver genes. Currently, it is a challenge to detect such clones due to low variant allele frequency (VAF). However, in individuals who do carry cancer-associated mutations, this process is referred to as clonal hematopoiesis of indeterminate potential (CHIP). Thus, in order to meet the definition of CHIP, one must carry driver mutations (*DNMT3A* and/or *TP53*, for example) at a VAF of 2% or higher.[9,10] CHIP by itself does not designate a malignant transformation or other clinical manifestations, but it does share common mutations that are recurrent in hematological disorders such as AML, MDS, myeloproliferative neoplasms (MPNs), and lymphomas.[10] Furthermore, for unknown reasons, only a fraction

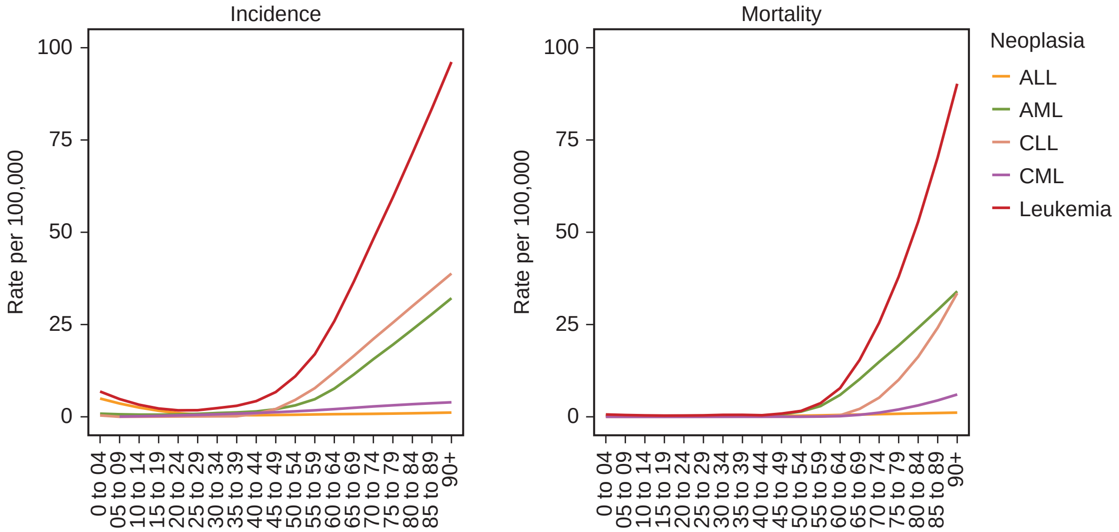

Figure 19.1 AGE-ASSOCIATION OF LEUKEMIA. Number of cases (incidence) and deaths (mortality) related to hematological malignancies. Rate represents the number of cases/mortality per 100, 000 habitants. *ALL*, Acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *CLL*, chronic lymphoid leukemia; *CML*, chronic myeloid leukemia. *(From Cancer Research UK, https://www.cancerresearchuk.org/health-professional/cancer-statistics/statistics-by-cancer-type/leukaemia#heading-Zero. Accessed March 2020.)*

of individuals with CHIP will actually undergo malignant transformation.[8] However, individuals carrying CHIP have a significantly increased risk of mortality that is largely accounted for an overall increased risk for cardiovascular diseases. Large cohort studies showed that individuals with CHIP have double the risk of developing coronary heart diseases and a four times higher risk to develop early-onset myocardial infarction (MI). CHIP also increases the risk of venous thrombosis 12-fold and is correlated with worse survival outcomes of post-MI-related congestive heart failure. Overall, CHIP is a strong indicator of poor prognosis for several distinct disorders including the development of hematological malignancies and cardiovascular disorders.[10]

Although CHIP is significantly more prevalent in elderly individuals, a causal relation between clonal hematopoiesis and aging and possibly other factors remains to be determined. Indeed, many healthy elderly individuals display clonal hematopoiesis. Specifically, if the mutations that define clones are not leukemia-driver mutations—i.e., occur at a non-fully annotated genetic loci or in genes that have not yet been implicated in malignant transformation—this process is referred to as age-related clonal hematopoiesis (ARCH).[9] Similarly as individuals with CHIP, individuals who display ARCH also have a higher risk of mortality. As a full catalog of leukemia-drives genes is lacking, CHIP and ARCH could represent similar processes (Fig. 19.2).[9]

Although the molecular mechanism of how clonal hematopoiesis arises is far from understood, it is clear that perturbations that occur at the multipotent progenitor and/or HSCs level affect how such clones will behave. As an example in the context of clonal hematopoiesis, loss-of-function mutations in *DNMT3A* are among the most prevalent in individuals displaying CHIP. This event likely provides mutated clones with an aberrant DNA methylation profile that results in a selective advantage over time, leading to clonal outgrowth.[2]

Even in individuals who do not display detectable levels of clonal hematopoiesis, physiological aging is likely to render clone selection during a lifespan, where HSCs that become more adapted to age-associated changes eventually will replenish mature blood cells. Interestingly, studies in human and other animal models have demonstrated multiple age-associated changes (mechanisms) that play an important role in HSC aging, and those are discussed in the following sections.

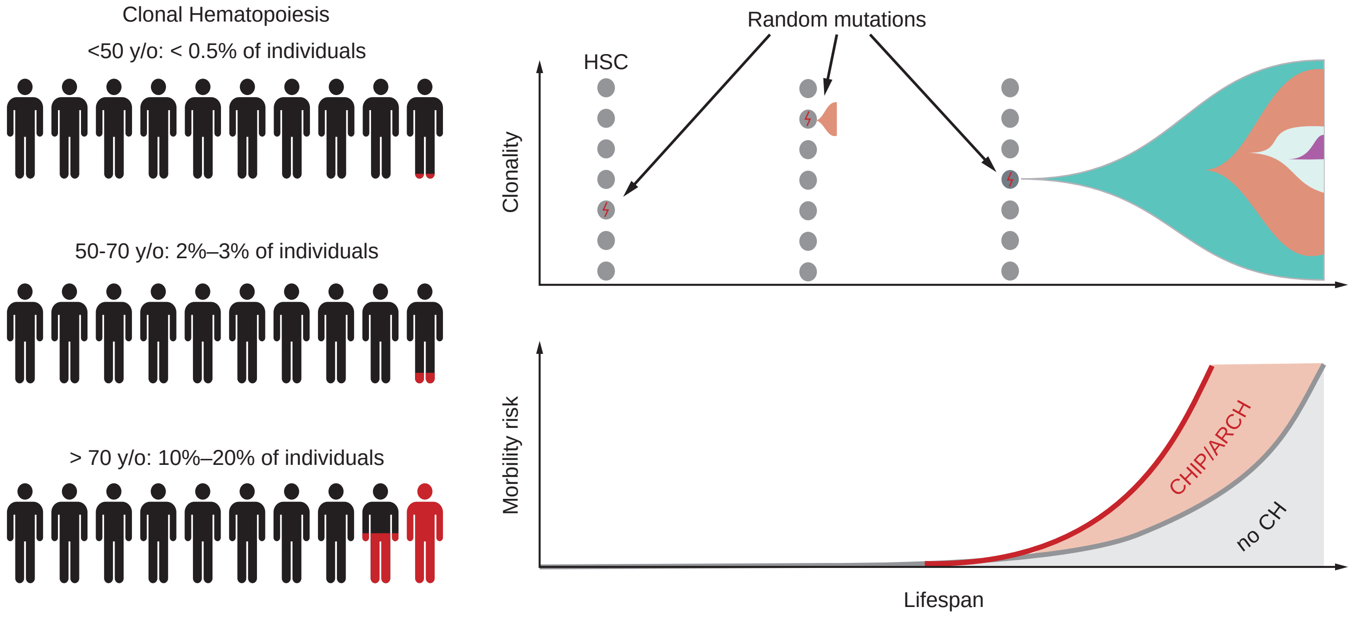
MECHANISMS OF HEMATOPOIETIC STEM CELL AGING

Many studies have examined which factors, mechanistically, contribute to HSC aging. It is important to note that most of our understanding of HSC aging is based on murine models. In general, mechanisms that contribute to HSC aging can be divided into intrinsic factors (DNA damage, autophagy and reactive oxygen species [ROS], and epigenetic drift) or extrinsic factors (BM microenvironment, senescence, and inflammation) (Fig. 19.3).[11–13]

INTRINSIC FACTORS

DNA Damage

Genomic instability and DNA damage are hallmarks of aging in different tissues.[1] Acquired mutations at specific loci primarily caused by DNA damage in HSCs can lead to clonal hematopoiesis in elderly individuals, as discussed previously. This suggests that aged HSCs are more susceptible to DNA damage compared to young HSCs. Indeed, aged HSCs display an increased number of γH2A foci—a widely used marker of DNA damage—and have difficulty in removing these foci, indicating impaired DNA repair. However, to what extent the functional decline of aged HSCs is caused by DNA damage is not yet clear.[12,13] It has been demonstrated that both young and aged murine HSCs can repair DNA equally effectively following induced DNA damage.[13] Although HSCs from mice lacking distinct genomic maintenance pathways exhibit decreased reconstitution and self-renewal capacity, HSCs in these mice are reduced in numbers, in contrast to normal aging where HSCs expand.[12–14] Telomere shortening, another hallmark of aging, is a specific kind of DNA damage. Early studies demonstrated that telomere length inversely correlated with lifespan of a cell, where older cells display shorter telomeres and progressively shorten at each cell division. Interestingly, murine serial transplantation studies revealed no change in telomere length, and HSC repopulation capacity was not improved by overexpressing telomerase.[13] Collectively, more studies are needed to clarify to what extent normal HSC aging in fact is caused by DNA damage.



Clonal Hematopoiesis

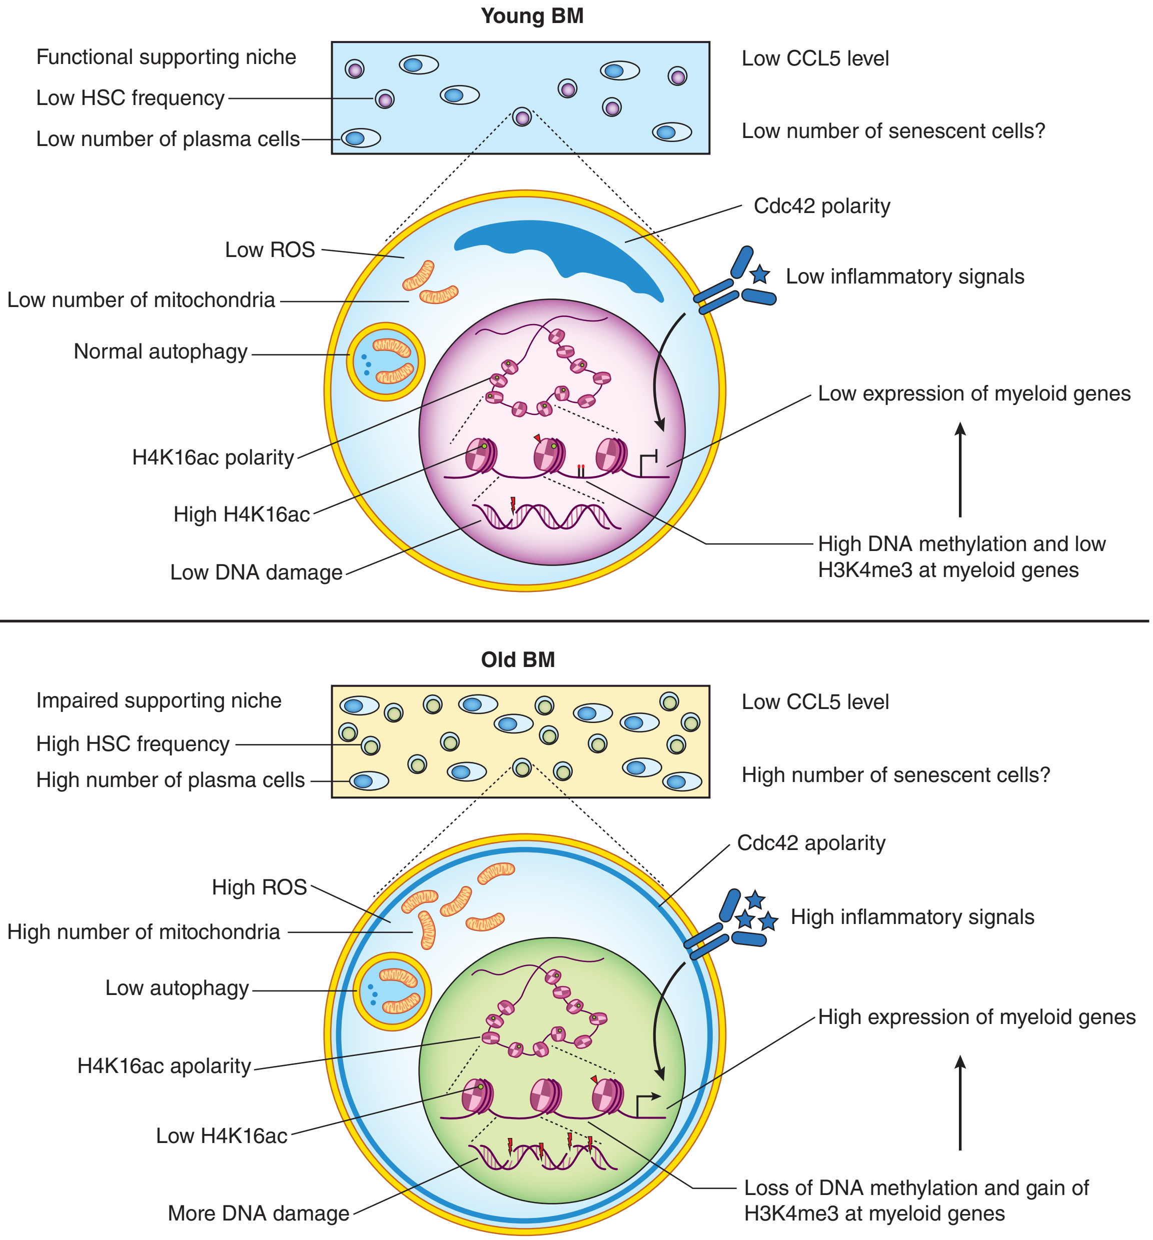
Lifespan

Figure 19.2 CLONAL HEMATOPOIESIS. The incidence of clonal hematopoiesis increases with age *(left)*. Somatic mutations occur during normal aging and are typically inconsequential. Some clones may acquire a proliferative advantage, and eventually, blood production will be oligoclonal *(right, top)*. If dominant clones result from leukemia driving mutations (e.g., DNMT3A, TP53), individuals are diagnosed with clonal hematopoiesis of indeterminate potential *(CHIP)*. Age-related clonal hematopoiesis *(ARCH)* refers to the acquisition of non-driver mutations at an older age. Both processes significantly increase the odds of hematological malignancies and mortality *(right, bottom)* compared to individuals who do not carry clonal hematopoiesis *(CH)*. *HSC*, Hematopoietic stem cell.



Young BM
Functional supporting niche
Low HSC frequency
Low number of plasma cells
Low CCL5 level
Low number of senescent cells?
Cdc42 polarity
Low ROS
Low number of mitochondria
Normal autophagy
Low inflammatory signals
Low expression of myeloid genes
H4K16ac polarity
High H4K16ac
Low DNA damage
High DNA methylation and low H3K4me3 at myeloid genes
Old BM
Impaired supporting niche
High HSC frequency
High number of plasma cells
Low CCL5 level
High number of senescent cells?
Cdc42 apolarity
High ROS
High number of mitochondria
Low autophagy
High inflammatory signals
High expression of myeloid genes
H4K16ac apolarity
Low H4K16ac
More DNA damage
Loss of DNA methylation and gain of H3K4me3 at myeloid genes

Figure 19.3 HALLMARKS OF HEMATOPOIETIC STEM CELL AGING. An overview of intrinsic factors and extrinsic factors that have been reported to contribute to HSC aging. *BM*, Bone marrow; *CCL5*, CC-chemokine ligand 5; *HSC*, hematopoietic stem cell; *ROS*, reactive oxygen species.

Autophagy and Reactive Oxygen Species

Autophagy is a self-catabolic process by which cellular components are sequestered into double-membrane vacuoles, generally associated with the recycling of organelles, and required for cellular hemostasis. Impaired autophagy can lead to the accumulation of toxic proteins and damaged mitochondria, which in turn induces metabolic stress.[12] Around one-third of aged murine HSCs exhibit high autophagy levels. This subpopulation shows a low metabolic state and a high regeneration potential, resembling young HSCs. The remaining population—with decreased autophagy levels—exhibits an activated metabolic state and impaired HSC self-renewal capacity.[13] Thus, loss of autophagy causes metabolic activation and similar myeloid bias as observed in aged HSCs.[13]

ROS—natural products of oxygen-based metabolic processes—are produced mainly by mitochondria. It has been shown that high levels of ROS generate oxidative cellular stress.[13,14] In general, HSCs are quiescent with low levels of metabolism and low ROS production. However, upon aging, HSCs start accumulating ROS, which then attenuates their fitness.[13,14] It has been shown that HSCs exposed to high ROS levels have age-associated phenotypes, for example, impaired long-term engraftment. The fact that the reduced colony-forming potential of ROS^{high} HSCs can be rescued by ROS inhibition further implies a role of ROS in HSC aging and presents potential pharmacological targets to counter age-associated HSC dysfunction.[13,14]

Epigenetic Modifications

Epigenetic modifications, including DNA methylation and histone modifications, are responsible for the regulation of gene expression without affecting the underlying DNA sequence—a change in phenotype without a change in genotype.[14] Epigenetic modifiers, generally characterized as writers, readers, or erasers, play essential roles in HSC self-renewal and differentiation.[15] As discussed, individuals displaying clonal hematopoiesis, specially CHIP, but also patients with MDS or full-blown AML, very frequently have acquired loss-of-function mutations in epigenetic genes, denoting the importance of this regulatory layer.[10,15] Moreover, in murine models, some epigenetic genes have been reported to be differentially expressed following HSC aging, suggesting that the epigenome is remodeled during aging.[13]

DNA methylation is often linked to transcriptional gene repression. Age-associated changes in the methylome occur, but their functional significance still remains controversial. However, regardless of whether overall hypo- or hypermethylation occurs in aged HSCs, similar patterns at specific loci have been found.[13] For instance, the Polycomb Repressive Complex-2 (PRC2), which deposits the repressive histone modification H3 lysine 27 tri-methylation (H3K27me3), targets genes that are DNA hypermethylated in aged HSCs,[13] suggesting a crosstalk between these two epigenetic marks.

Histone modifications, including active and repressive marks, impact gene expression by altering chromatin structure to render it more or less accessible to transcription factors and the transcriptional machinery or by recruiting "readers" of the histone code.[15] There are multiple histone modifications, but profiles of certain typical modifications occurring in young or aged HSCs have already provided insight into HSC aging.[13–16] For example, global levels of H4 lysine 16 acetylation (H4K16ac), an activating histone modification, have been shown to be elevated in aged HSCs. Interestingly, H4K16ac also affects HSC polarity changes that have been reported to be controlled by a small Rho GTPase, cell division control protein 42 (Cdc42).[13,14] The molecular function of Cdc42 is discussed in the following section.

Epigenetic regulation also provides a potential mechanism underlying myeloid skewing. It has been observed that some myeloid genes gain active histone modifications such as H3 lysine 4 tri-methylation (H3K4me3) and lose DNA methylation in aged HSCs, leading to transcriptional up-regulation of these genes.[16] This raises the possibility that targeting the epigenetic state can potentially restore the function of aged HSCs. Indeed, induced pluripotent stem (iPS) cells generated from reprogrammed young and aged hematopoietic progenitors showed similar repopulating capacity and appear to be rejuvenated.[13]

Chromatin Architecture and Polarity

Recently, overall chromatin architecture has been implicated as a pivotal player of gene expression, cell division, fate determination, growth and development, disease, and even genome evolution.[13] In HSC biology, disease-associated mutations of proteins involving 3D chromatin organization have occasionally been observed and linked to hematopoietic disorders in the elderly.[13] Studies of chromatin architecture during HSC cell division revealed that young HSCs display a more "asymmetrical" division pattern—where one of the daughter cells retains the stem cell properties—whereas aged HSCs have preferentially "symmetrical" division patterns due to loss of cell polarity, resulting in reduced regenerative capacity and lymphoid potential.[13] Cdc42 activity is elevated in aged HSCs and correlates with the loss of polarity of aged HSCs. Pharmacological reduction of Cdc42 activity restored the level and spatial distribution of H4K16ac to a similar status to that seen in young HSCs and eventually rejuvenated aged HSCs.[12–14]

EXTRINSIC FACTORS

Bone Marrow Microenvironment

The spatial location where HSCs reside also has a significant impact on their activity. This microenvironment, termed a BM "niche," is composed of a plethora of hematopoietic and non-hematopoietic cells such as mesenchymal stem cells, osteoblasts, endothelial cells, macrophages, among others.[17] These supporting populations are able to regulate quiescence, self-renewal, proliferation, and differentiation of HSCs.

Collectively, niche cells regulate HSCs through the production of diverse cytokines, extracellular matrix proteins, and adhesion molecules.[17] This raises the possibility that age-associated BM niche remodeling can influence the functioning of HSCs. Although recent studies have started to elucidate the mechanisms through which the niche regulates HSCs, limited data are available on the differences between young and aged HSC niches.[17]

Classic BM transplantation showed that a young BM niche failed to rescue aging stem cell phenotypes when aged HSCs were transplanted into irradiated young recipients, suggesting that features observed upon HSC aging are mainly caused by intrinsic changes.[12] However, young HSCs showed impaired homing and engraftment capability when transplanted into old recipients, while aged HSCs showed higher engraftment and less myeloid output when exposed to a young niche, suggesting a negative impact of the aged microenvironment on hematopoiesis.[17] Importantly, a recent study showed that BM plasma cells increased in number with age and that the depletion of these cells reduced myeloid cell production in aged mice.[18] In the future, greater effort is needed to investigate the roles of the BM niche in the context of HSC aging.

Senescence

Cellular senescence is another hallmark of aging, and the removal of senescent cells (SCs) can prevent or delay tissue dysfunction and extend the lifespan.[12,14] It has been reported that the senolytic drug navitoclax (ABT263), a specific inhibitor of anti-apoptotic proteins, selectively kills SCs in culture in a cell type- and species-independent manner by inducing apoptosis. ABT263 treatment also clears SCs in normally aged mice and improves the long-term engraftment potential of aged HSCs following serial transplantation.[14] It is likely SCs impair BM HSC function due to the senescence-associated secretory phenotype (SASP), where inflammatory cytokines, such as interleukin 6 (IL-6), are secreted. The impact of inflammatory cytokines will be further discussed in the following section.

Inflammation

Inflammation is defined as a protective immune response, which underlies a variety of pathophysiological processes that are in part caused by infection and tissue injury/damage. HSCs are needed for multi-lineage differentiation to replenish immune effector cells consumed during inflammation.[19] Actually, HSCs can also directly sense inflammatory signals since a broad spectrum of inflammatory cytokine/chemokine receptors are expressed by HSCs,[11,19] directly influencing HSC fate decisions. It has been shown that HSCs are activated and produce more myeloid cells but fewer lymphoid cells in response to inflammation.[11,19] Many studies have demonstrated that signaling via inflammatory cytokines impacts long-term HSC potential.[11,19]

In an aging context, the role of inflammation is more prominent. Chronic inflammation occurs frequently in the elderly and is associated with multiple age-related diseases—referred to as "inflammaging."[11,19] Age-related functional alterations (such as impaired repopulation potential and myeloid bias) of HSCs are very reminiscent of those seen under inflammatory stresses. Moreover, aged HSCs demonstrate increased myeloid output in response to inflammatory challenges as compared to young HSCs.[19] Elevated levels of the pro-inflammatory CC-chemokine ligand 5 (CCL5) have been reported in the old BM niche, which is likely responsible for myeloid skewing of aged HSCs.[14,17] Furthermore, it has been shown that tumor necrosis factor α (TNF-α) can drive myeloid regeneration, and the treatment of aged mice with interleukin 1 (IL-1) and TNF-α inhibitors reduces myelopoiesis.[18,20] Interestingly, an HSC-specific TNF-α signature is enriched in aged and malignant HSCs,[20] supporting the idea that inflammation plays an important role in HSC aging. To note, positive feedback between aging and inflammation may exist, as more myeloid cells, which secrete pro-inflammatory cytokines, are produced as HSCs age. As a consequence, those cytokines in turn promote myelopoiesis which then promotes HSC aging.[11]

FUTURE PERSPECTIVES

Hematopoietic aging is a very complex and multifactorial phenomenon, involving both intrinsic and extrinsic factors which directly impact HSCs, resulting in a plethora of age-associated clinical manifestations. In the context of clonal hematopoiesis, it remains unknown why ARCH/CHIP arises and what the dynamics of clonal growth within an individual are. For example, it is possible that clonal hematopoiesis is affected by inflammatory signals and that recurrent infections provoke the emergence of dominant clones. Further advancements and increased sensitivity of genomic sequencing will shed light on the actual frequency of mutations and should entail which—known or unknown—mutations are actually related to a poor prognosis. This layer of information, which is progressively being introduced into clinical diagnostics, provides two major advantages. First, a detailed characterization of clones should inform if patients carry premalignant traits and therefore will assist with early diagnosis. Second, the nature of such mutations can potentially directly impact the treatment regime for the patient, focusing on the most effective chemotherapeutic agent against a particular clone for the development of a chemopreventive clinical strategy. Possibly, age-associated premalignant clones may be targetable. Thus, the detection of premalignant stages may not only improve survival but also dictate the specificity of the treatment.

Yet, there are multiple aspects of HSC aging that have not been elucidated. This includes the identification of alternative, novel, molecular mechanisms that may impact the age-associated HSC fate. Most studies have focused on stem cell-intrinsic mechanisms, while our knowledge of extrinsic factors remains limited. The elusive stem cell niche plays an important role in HSC maintenance and its alterations with age very likely impact HSC aging. Many distinct cell types in the niche have been shown to be involved in HSC regulation, where the role of most cells in the BM microenvironment remains to be determined. Changes in intrinsic factors with age may well be the consequences of alterations in the niche. A series of studies have shown that targeting intrinsic aging drivers can delay or, to some extent, reverse the aging process. Intervention at the level of the niche provides novel targets for future therapies resulting in the delay of HSC aging and treating age-related hematopoietic disorders.

Moreover, recent efforts have been focused on understanding the mechanisms behind non-malignant and malignant HSC heterogeneity. These studies will provide fundamental aspects of clonal dynamics that will further refine our understanding and will allow the development of novel therapeutic approaches to mitigate the effect of aging on hematopoiesis.

PART III IMMUNOLOGIC BASIS OF HEMATOLOGY

CHAPTER 20

DENDRITIC CELL BIOLOGY

Cansu Cimen Bozkus and Nina Bhardwaj

Dendritic cells (DCs), originally discovered in 1973 by Ralph M. Steinman and Zanvil A. Cohn and named after their distinct stellate morphology, are important regulators of immune responses.[1] Specialized in antigen acquisition, processing, and presentation, the hallmark of DCs is their ability to induce naïve T cell activation and effector differentiation. DCs also interact with other immune cells, such as B cells, natural killer (NK) cells, innate lymphoid cells, and secrete immunomodulatory molecules, thereby mediating the induction and maintenance of immunity and tolerance.[2] This chapter describes the current knowledge of DC ontogeny and function as well as the utility of DCs as immunotherapeutic agents in clinical applications.

DENDRITIC CELL SUBSETS AND DEVELOPMENT

DCs are highly heterogeneous and classified into subsets based on their developmental origin, anatomical location, function, expression profile of transcription factors, and phenotypic markers. DC development involves four stages, namely, hematopoietic precursors, DC precursors (pre-DC), immature DCs (imDCs), and mature DCs (mDCs). All DCs originate in the bone marrow and are continuously produced in a steady rate from $CD34^+$ hematopoietic stem cells (HSCs) in a process primarily directed by Fms-like tyrosine kinase 3 ligand (Flt3L) and granulocyte-macrophage colony-stimulating factor (GM-CSF).[3] According to the classical model of hematopoiesis, HSCs give rise to common myeloid precursors (CMPs), excluding lymphoid lineage potential, and CMPs then develop into monocyte DC precursors (MDPs), excluding granulocyte potential. MDPs subsequently transition into common DC progenitors (CDPs). MDPs give rise to inflammatory DCs (iDCs), while CDPs give rise to pre-DCs that migrate out of bone marrow into lymphoid and nonlymphoid organs, where they differentiate into major DC subsets: conventional DCs (cDCs) and plasmacytoid DCs (pDCs).[4] Notably, pDCs are also produced by the lymphoid progenitors in the steady state (Fig. 20.1).[5–7] Therefore, the progressive lineage specification that limits alternative fate potential, described by the classical hematopoiesis model, should not imply a solid state of cell fates.

This section summarizes the transcriptional and phenotypical characteristics associated with distinct DC subsets while concentrating on human DCs with little reference to murine models. Readers are encouraged to seek additional information provided in other comprehensive reviews.[3,8]

Broadly, DCs are defined as mononuclear immune cells that lack key lineage markers for T cells (CD3), B cells (CD19 and CD20), and NK cells (CD56). Additionally, DCs express high levels of major histocompatibility complex (MHC) class II molecules, such as HLA-DR. Expression of distinct surface markers and transcription factors are utilized to classically categorize DCs into four major terminally differentiated subsets: cDCs, pDCs, iDCs, and Langerhans cells (LCs).[3]

Conventional Dendritic Cells

cDCs comprise two major subsets, cDC1s and cDC2s. Both subsets express CD11c and MHC class II molecules. In humans, cDC1s are characterized by the expression of CD141 (BDCA-3), CLEC9A, XCR1 and CADM1, whereas cDC2s express CD1c (BDCA-1), SIRPα (CD172), and CD11b. In mice, cDC1s also express XCR1, CLEC9A, CADM1, as well as CD8a/CD103 and cDC2s express SIRPα, CD4, and CD11b.[9] Although these markers define the cDC1 subset quite precisely, cDC2 markers are less specific and do not address the heterogeneity within the cDC2 subset. Recent studies by independent groups have identified that the classically defined cDC2 subset comprise multiple subpopulations,[10,11] which are detailed in the "New Developments in DC Classification" section.

The development of cDC subsets is regulated by distinct transcriptional programs. cDC1s express interferon regulatory factor (IRF) 8, basic leucine zipper transcriptional factor ATF-like 3 (Batf3), and DNA-binding protein inhibitor 2 (ID2). cDC2s express IRF4 and Kruppel-like factor 4 (Klf4). Notch signaling also plays an essential role in the development and differentiation of cDCs. Evidence for the importance of Notch signaling in DC programming comes from in vitro cultures both in murine and human systems, in which DCs are generated in the presence of OP9 cells, a stromal cell line supporting the differentiation of HSCs.[12] Specifically, in the context of human cells, expanding cord blood or peripheral blood $CD34^+$ precursor cells with key factors for DC growth and differentiation, namely Flt3-L, SCF, IL-7, and thrombopoietin (TPO) and subsequently inducing their differentiation in the presence of OP9 feeder cells, generated primarily pDCs with small frequencies of cDCs. In the same system, when Notch ligand DLL1 expressing OP9-DLL1 cells were used as feeders, pDC generation was suppressed and the proportion of cDCs, particularly cDC1s, were greatly increased, which transcriptionally, phenotypically, and functionally resembled their primary blood cDC1 counterparts.[13] Other studies in murine models have also demonstrated nonredundant roles for Notch signaling in cDC2 differentiation and function, particularly in T follicular helper (T_{FH}) cell differentiation and induction of B cell responses during infection.[14,15]

Both cDC subsets are known for their unique efficacy for priming naïve T cells and inducing their functional polarization. Additionally, cDC1s, expressing an array of immunoregulatory molecules, are key for tolerogenic regulation.[16] cDC1s are superior to cDC2s at antigen cross-presentation, a process through which exogenous antigens are acquired and presented on MHC class I molecules, thereby inducing $CD8^+$ T cell responses.[17] While cDC1s can also activate $CD4^+$ T cells and polarize them toward a Th1 phenotype, cDC2s are the main subset specialized in MHC class II-mediated antigen presentation. cDC2s efficiently activate $CD4^+$ T cells and induce their polarization toward Th1, Th2, and Th17 phenotypes in specific contexts. cDC2 is

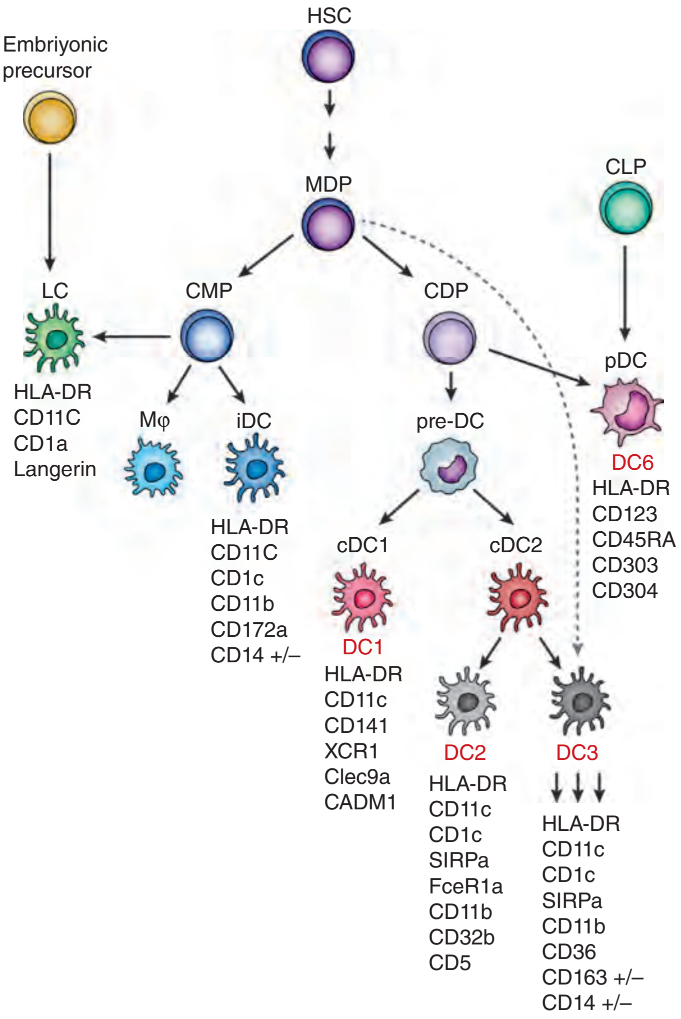

Figure 20.1 SIMPLIFIED MODEL OF DENDRITIC CELL HEMATOPOIESIS AND SUBSET CLASSIFICATION. The arrows indicate the lineage hierarchy. Classically defined DC subsets are also annotated in red based on their shared characteristics with more recently defined DC subset classifications, namely DC1-6, which are still undergoing modification. A simplified list of markers delineating different DC subsets is also described. *CDP*, Common dendritic cell progenitors; *CLP*, common lymphoid precursors; *CMP*, common myeloid progenitors; *HSC*, hematopoietic stem cells; *MDP*, macrophage dendritic cell progenitors; *Mφ*, macrophages.

the most frequent DC population and found in blood, lymphoid, and non-lymphoid tissues, while cDC1s are thought to primarily reside in the lymph nodes (LNs) and found in trace numbers in the blood. Another distinct feature between cDC1 and cDC2 subsets is the differential expression of pattern recognition receptors (PPRs), which recognize conserved molecules displayed by pathogens or damaged cells. cDC1s express Toll-like receptors (TLRs) 3 and 8. Due to TLR3 triggering, cDC1s have the unique ability to produce type III interferons, which contribute to antiviral and antitumor immunity.[16–19] cDC2s express a wide range of PRRs, TLRs 1–8, and produce IL-23, a critical cytokine for innate defense. Hence, cDC2s mediate antimicrobial responses against a greater variety of pathogens.[20]

Plasmacytoid Dendritic Cells

pDCs are distinguished by high levels of CD123, CD303 (BDCA-2), and CD304 (BDCA-4) and the lack of CD11c, AXL, Siglec-6 expression.[11] Transcription factor Tcf4 specifically regulates the development of pDCs.[21] pDCs can also be recognized by their distinct morphology resembling secretory plasma cells with a round shape and well-defined endoplasmic reticulum (ER).[22,23] Although small fractions of pDCs may be found in blood, they primarily reside in lymphoid tissues. The hallmark of pDCs is the ability to produce large quantities of type I interferons, IFN-α/β, although they have been shown to produce type III interferon, IFN-λ, as well.[24,25] pDCs produce interferons in response to recognition of viral RNA or DNA through TLR7 and TLR9, respectively, and exert potent antiviral effects. The activation of TLR7/9 may also lead to the production of tumor-necrosis factor-α (TNF-α) and IL-6 by pDCs, which contributes to pDC maturation, antibody production by B cells, and generation of tolerogenic T cells.[26–29]

pDCs lack the capacity for antigen presentation and T cell stimulation in an immature state, suggesting they are less important for the activation of naïve T cells. However, recent studies have shown that upon activation, a subset of pDCs differentiates into a more cDC-like state by adopting a dendritic morphology, upregulating HLA-DR, CD80, and CD11c and downregulating TCF4. This activated pDC subpopulation has antigen-presenting capacity and can prime T cells, highlighting the high degree of DC heterogeneity and plasticity.[23,30]

Inflammatory Dendritic Cells

iDCs appear under inflammatory conditions, accumulate at the inflammation site, and disappear upon resolution of inflammation. They are characterized by the expression of CD11c, CD11b, CD172a, CD14, and CD1c. iDCs also express the Zbtb46 transcription factor, which is specific to DC lineage. Functionally, iDCs can process and present antigens to T cells and induce T call activation and polarization. They can also produce inflammatory cytokines, including IL-6, IL-1β, and IL-23.[31] Based on their gene signature similarities, iDCs are proposed to be in vivo equivalents of monocyte-derived DCs (moDCs), which are differentiated in in vitro culture systems most commonly with the addition of GM-CSF and IL-4 (Fig. 20.2).[31] However, the role of GM-CSF for the generation of iDCs in vivo is not fully understood. In mice, while GM-CSF or its receptor were dispensable, M-CSF receptor was shown to be essential for iDC differentiation and function.[32]

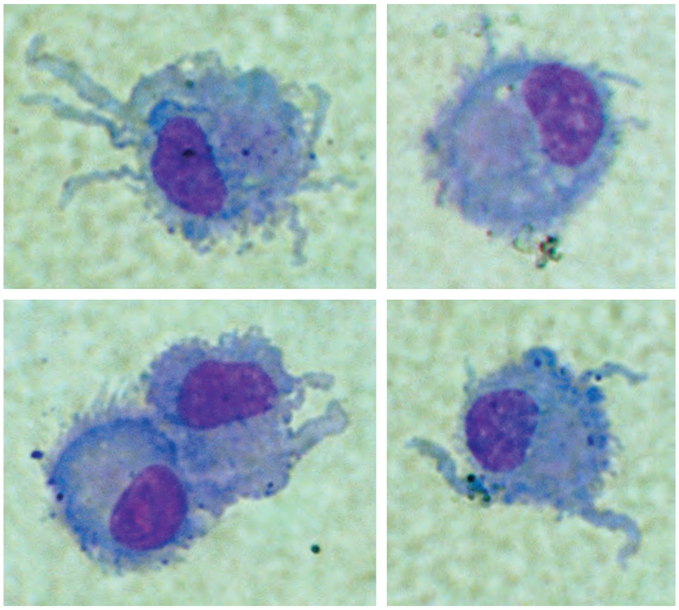

Figure 20.2 EXAMPLES OF MONOCYTE-DERIVED MATURE DENDRITIC CELLS. The monocytes were enriched by plastic adherence, cultured with interleukin-4 (IL-4) and granulocyte-macrophage colony-stimulating factor (GM-CSF) for 6 days, and underwent maturation with IL-1, IL-6, tumor-necrosis factor-α (TNF-α), and prostaglandin E_2 (PGE_2) for 24 hours.

Langerhans Cells

LCs are tissue-resident cells found in the epidermal layer of the skin. LCs share common precursors with macrophages and are classified in the same lineage as macrophages. Moreover, like other tissue-resident macrophages, LCs can proliferate in differentiated states. Importantly, LCs also have DC-like capabilities, such as acquiring antigens, migrating to LNs, and activating T cells.[33–35] LCs express CD1a and Langerin (CD207). They also contain Birbeck granules in their cytoplasm, which distinguishes them from the other Langerin expressing dermal DCs.[36] Ontologically, LCs arise from yolk sac and fetal liver progenitors. These progenitors seed the skin during embryogenesis and differentiate into LCs in a transforming growth factor-β (TGF-β) and M-CSF receptor-dependent process.[35,37] Once established, LCs are maintained locally by self-renewal under steady state conditions.[38,39] However, LCs also have a hematopoietic origin as circulating hematopoietic precursor cells have been shown to replenish the LC population during skin inflammation.[33,38]

Serving as an immunological barrier to the external environment, LCs are efficient at recognizing foreign antigens since they express a variety of PRRs including Langerin and a large repertoire of TLRs.[40] Upon recognition of foreign antigens, LCs upregulate MHC class II and other co-stimulatory molecules and migrate to LNs, where they prime CD4$^+$ T cells and induce their polarization into Th1, Th2, Th17, and Th22 phenotypes.[41–43] LCs can also prime CD8$^+$ T cells under certain circumstances.[44] LCs also play a role in establishing immune tolerance, for example by presenting self-antigens to T cells in the LNs in homeostatic conditions,[45] as well as by inducing regulatory T cells in the skin that suppress allergic skin reactions.[46,47]

New Developments in Dendritic Cell Classification

The understanding of DC developmental pathways and subsets is continuously being improved due to advances in high-dimensional, single-cell technologies by more sensitively defining the identities of this highly heterogenous population. Utilizing blood cells isolated from healthy donors, which were enriched for HLA-DR expression and lack of lineage markers (CD3, CD56, CD19, CD14), Villani et al., performed single-cell RNA sequencing (scRNAseq) and unbiased clustering analysis to identify and compare DC populations. They identified six distinct DC subpopulations (DC1-6). Gene signatures of most of these clusters aligned well with traditionally defined subsets. DC1, DC6, and DC4 clusters mapped to cDC1, pDC, and CD16$^+$ monocytes, respectively. Two distinct clusters, DC2 and DC3, mapped to cDC2 subset, suggesting a new subdivision within the classical cDC2 population. Additionally, a previously unknown subset was identified. Despite expressing markers in common, cells in this cluster (DC5) differed from pDCs by their morphological resemblance to cDCs and their potent capacity to activate T cells. This novel subset was defined by the expression of AXL and SIGLEC6, hence named “AS DCs,” and corresponded to 2% to 3% of blood DCs.[11] Corroborating these results, Alcantara-Hernandez et al., unbiasedly evaluated the phenotypic heterogeneity of human blood and tissue DCs by utilizing mass spectrometry (CyTOF) and identified a cluster corresponding to AS DCs and subdivisions within the cDC2 population.[30] Such subdivisions within the cDC2s were further delineated by Dutertre et al., demonstrating that cDC2s comprise a CD5$^+$ and three CD5$^-$ subpopulations (CD163$^-$, CD163$^+$CD14$^-$, and CD163$^+$CD14$^+$ cells), with CD5$^+$ and CD5$^-$ cells resembling DC2 and DC3s, respectively, as described by Villani et al.[10] Another recent scRNA-seq study, by Bourdely et al., also identified the DC3 subset in blood and defined DC3s as a separate subset bearing monocyte markers (e.g., CD163, CD14) and features of cDC2s. Further supporting the distinction of the DC3 subset, they identified a DC3-restricted progenitor population.[48] Independently, Cytlak et al. found that the heterogeneity of DC2 and DC3 subsets was associated with distinct developmental pathways dependent on differential IRF8 requirements.[49]

DENDRITIC CELL MATURATION

Under steady state conditions DCs commonly exist in an immature form. Upon detecting tissue disturbances and danger signals through their PRRs, DCs undergo phenotypical and functional changes, enhancing their capacity to stimulate T cells. This process is called DC “maturation” or “activation.”

DC maturation can be induced by a variety of stimuli such as microbial products, danger signals released by damaged cells, cytokines, and cellular crosstalk (e.g., ligation of CD40).[50–52] To sense such diverse stimuli, DCs express a wide array of PRRs, localized both at the cell membrane and the cytoplasm. PRRs recognize pathogen-associated molecular patterns (PAMPs), derived from microorganisms, or danger-associated molecular patterns (DAMPs), secreted by damaged cells. Membrane-bound PRRs include TLRs and C-type lectin receptors (CLRs). Cytoplasmic PRRs include NOD-like receptors (NLRs) and retinoic acid (RA)-inducible gene (RIG)-I-like receptors (RLRs). Other receptors such as scavenger receptors (SRs) and integrins can also serve as PRRs.[53] Another major group of PRRs is secreted proteins, including complement receptors and collectins. PRRs are further classified into subgroups based on their ligand specificity and function. Table 20.1 summarizes the properties of PRRs.[54–58]

imDCs continuously sample their surroundings and capture antigens via endocytosis, a process by which cells internalize extracellular substances. DCs utilize multiple endocytic mechanisms to acquire external antigens: phagocytosis (ingestion of large particles, e.g., pathogens, apoptotic cells), micropinocytosis (engulfing extracellular liquid and dissolved molecules), and receptor-mediated endocytosis.[59] Upon engagement of PRRs by inflammatory stimuli and induction of maturation, DCs downregulate endocytosis, restricting antigen capture after the initial stimulation.[60] Concomitantly, DCs upregulate cell surface expression of MHC class II molecules and co-stimulatory molecules (e.g., CD80, CD86), which are facilitated by DC-LAMP and CD83, two key markers that distinguish mDCs.[61,62] Further augmenting the efficacy of antigen presentation to T cells, DC maturation increases the half-life of MHC molecules and enhances lysosomal acidification and antigen loading onto MHC-II. Mature DCs also upregulate CCR7, a homing receptor, and migrate to LNs in response to chemokines such as CCL-19 and CCL-21. In the LNs, mDCs present antigens to T cells, both non-self and self, and induce T cell polarization into cytotoxic or tolerogenic states, respectively.[63] The immunogenic or tolerogenic function of DCs also depends on the type of stimuli that induce their maturation. DCs may produce pro-inflammatory, for example, IL-12, IL-6, IL-1β, or anti-inflammatory, for example, IL-10, TGF-β, cytokines in response to different stimuli, which impacts T cell polarization.[64] Tolerogenic DCs may induce the formation of regulatory T cells (Tregs), suppressing immune responses.[65] Therefore, DCs are key mediators of both immunity and tolerance.

ANTIGEN PROCESSING AND PRESENTATION

DCs are the most efficient antigen-presenting cell (APC) population in vivo. Through specialized mechanisms, DCs capture both exogenous and endogenous antigens, process these antigens, and present them in the context of class I and class II MHC molecules to CD8$^+$ and CD4$^+$ T cells, respectively (Fig. 20.3). DCs also present lipid antigens to T cells by CD1 molecules.[66]

MHC Class I Antigen Presentation (Endogenous Route)

Like all nucleated cells, DCs express MHC-I molecules. Antigens bound to MHC-I molecules are typically generated endogenously within the cytosol. Such endogenous antigens can be derived from both self and non-self molecules, for example, mutated or microbial proteins, respectively. Therefore, the MHC-I antigen presentation

pathway is critical for mediating immune detection of transformed or infected cells.

To bind to MHC-I molecules, antigens need to be broken down into certain lengths of peptides (commonly 8 to 11 amino acids). Antigenic peptides are initially generated by proteasome degradation and peptidase trimming in cytosol and then are translocated to the ER lumen by transporter associated with antigen processing (TAP). In the ER, a transient multi-subunit peptide loading complex (PLC) is formed, which comprises TAP, ERp57, and chaperon proteins tapasin, calreticulin, and calnexin. Interactions between these proteins and MHC-I heavy and light chains (β2-microglobulin) facilitate the assembly of MHC-I and retain empty MHC-I in a peptide receptive state within the PLC.[67] PLC mediates the loading of antigenic peptides onto newly synthesized MHC-I. Tapasin promotes the binding of high-affinity peptides to MHC-I by increasing the dissociation rate of suboptimal peptides.[68] Further enhancing the optimal peptide–MHC (pMHC) binding, antigenic peptides may be further trimmed by ER aminopeptidases (ERAP1/2) to increase conformational stability.[69] Once loaded with the optimal peptide, MHC-I molecules are stabilized and routed to the cell surface, where they can present the antigenic peptide to $CD8^+$ T cells, inducing their cytotoxic functions.

MHC Class II Antigen Presentation (Exogenous Route)

MHC-II molecules bind to peptides that are derived from extracellular proteins and from self-proteins that are degraded in the endosomal pathway. While all nucleated cells express MHC-I, only APCs express MHC-II. Although MHC-I and MHC-II molecules are structurally similar, the peptide-binding groove of MHC-II is more open and hence accommodates longer antigenic peptides (10 to 30 amino acids). Like MHC-I, the assembly of MHC-II molecules also occurs in the ER. MHC-II in the ER associates with the invariant chain (Ii) protein, which acts as a pseudopeptide to stabilize MHC-II and targets MHC-II molecules to late endosomal compartments called MHC class II compartment (MIIC) to encounter antigenic peptides. Antigenic peptides are generated in the MIIC by proteolytic degradation enabled by the acidic pH and resident proteases called cathepsins. The same proteases also degrade the Li protein bound to MHC-II, leaving a fragment called class II-associated invariant chain peptide (CLIP) intact as CLIP is bound to the MHC-II peptide-binding groove and hence protected. The chaperone protein HLA-DM catalyzes the replacement of CLIP by the antigenic peptides that bind to MHC-II with high affinity.[70,71] Antigen loading to MHC-II is further controlled by HLA-DO, another chaperone protein that pairs with HLA-DM and restricts HLA-DM activity only to acidic compartments.[72] Peptide-bound MHC-II are then transported to the cell membrane, where they can present the antigenic peptide to cognate $CD4^+$ T cells and induce helper T cell-mediated immunity.

Cross-Presentation

Cross-presentation is the process by which APCs present exogenous antigens on MHC class I molecules. This process is important for immune surveillance as it allows APCs, which are not transformed or infected themselves, to trigger cytotoxic immune responses or to induce cross-tolerance. DCs are considered the most efficient cross-presenting cells. The cross-presentation capacity of DCs varies among subsets and is influenced by the type of antigen, the inflammatory stimuli triggering PRRs and the endocytic receptor repertoire of DCs.[73,74]

DCs can acquire exogenous antigens from various sources, including apoptotic cells, necrotic cells, antibody-opsonized cells, immune complexes, heat shock proteins, exosomes, and exchange of antigen containing vesicles through dynamic synapses formed between DC subsets, and even nibbling of live cells.[75,76] Mechanistically, cross-presentation occurs via two major pathways, the cytosolic and the vacuolar pathways. In the cytosolic pathway, endocytosed antigens are transferred to cytosol, where they are degraded by the proteasome. These antigenic peptides then may translocate either to the ER or back to the endosomes to be loaded onto MHC-I. In the vacuolar pathway, antigens are degraded by lysosomal proteases and loaded onto recycling MHC-I in endocytic compartments. Signaling through TLRs has been reported to promote cross-presentation by inducing the accumulation of the MHC-I in the endosomes.[77] However, the exact

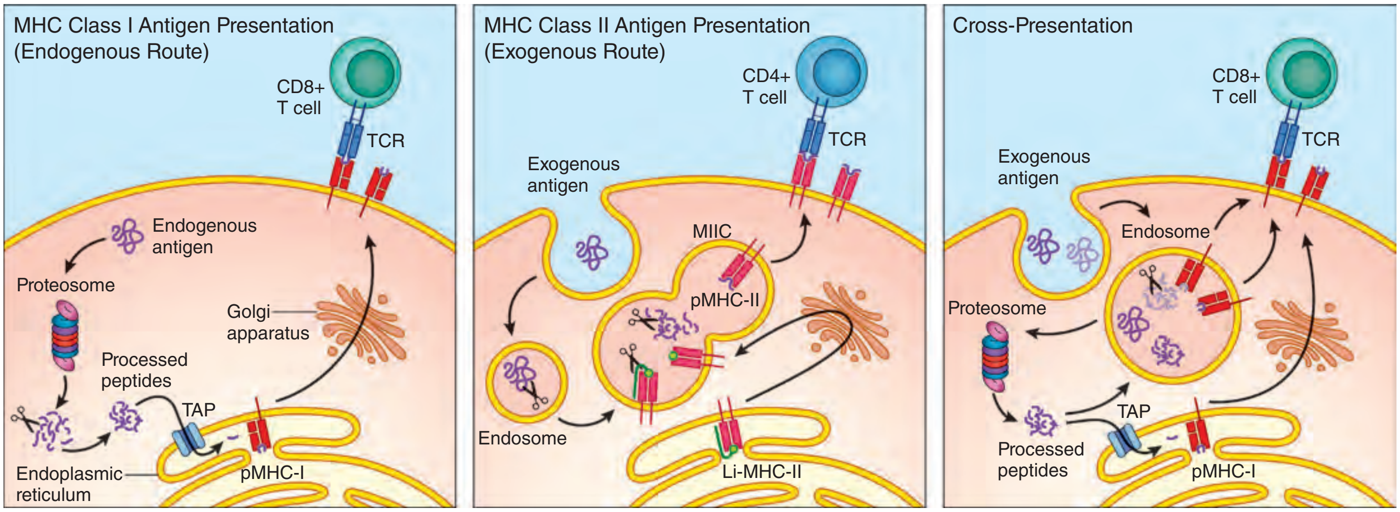

Figure 20.3 ANTIGEN PRESENTATION PATHWAYS IN DENDRITIC CELLS. The classical pathway for MHC class I antigen presentation *(left)* involves degradation of endogenous antigens into peptides by the proteasome followed by transport into the endoplasmic reticulum (ER) by the transporter associated with antigen processing (TAP). In the ER, peptides are loaded onto the newly synthesized MHC class I molecules, mediated by peptide loading complex, and further trimmed for conformational stability. Subsequently, peptide–MHC class I (pMHC-I) complexes are transported to the plasma membrane. For MHC class II antigen presentation *(middle)*, MHC-II molecules are assembled in the ER, where they associate with the invariant chain (Ii) protein. Li-MHC-II complex is then transported to endosomes called MHC class II compartment (MIIC). Proteases in the MIIC degrade Ii, leaving class II-associated invariant chain peptide (CLIP) intact in the MHC-II peptide-binding groove. HLA-DM catalyzes the exchange of CLIP by high-affinity antigenic peptides, which are endocytosed material (from both exogenous or endogenous sources) degraded by proteases in the MIIC. Peptide-bound MHC-II (pMHC-II) are then transported to the cell membrane. Two main pathways of cross-presentation *(right)* have been described that allow the presentation of exogenous antigens in association with MHC class I molecules. Antigens endocytosed or phagocytosed can be cleaved into peptides by proteases and loaded onto recycling MHC-I molecules within the same phagosome or on the cell surface (vacuolar pathway, shown in *light purple*). Alternatively, antigens may escape from the endosome and enter the cytosol (cytosolic pathway, shown in *dark purple*) to be processed via the classical MHC class I pathway. It has been suggested that elements of ER can be associated with phagosomes, allowing the transfer of antigens into the cytosol by the ER-associated degradation (ERAD) pathway and degradation by the phagosome-associated proteasome. The precise mechanisms and the locations of antigen processing in cross-presentation remain to be fully understood.

mechanisms and their relative contribution to cross-presentation are not yet fully understood.

An alternative mechanism for antigen presentation by DCs is cross-dressing. DCs can acquire fully functional pMHC complexes from other cells via trogocytosis (transfer of cell membrane patches), exosomes (vesicles that contain cellular constituents), or tunneling nanotubes. This process is called cross-dressing and allows rapid antigen presentation without the processing of antigens. DCs can acquire both MHC-I and MHC-II molecules by this method and elicit T cell responses.[78]

DENDRITIC CELL-MEDIATED IMMUNE RESPONSES

DCs are the sentinel cells of the immune system, constantly monitoring their external environment. Through their interactions with other immune cell populations, DCs initiate and orchestrate the appropriate immune responses against infectious diseases and cancer, as well as inducing immunological tolerance (Fig. 20.4).

T Cells

The hallmark function of DCs is to orchestrate T cell responses. By guiding T cell activation and differentiation in response to the inflammatory insults, DCs serve as a central bridge between innate and adaptive immunity. T cell priming by DCs takes place primarily at the LNs, which are specialized immune organs that are linked by lymphatic vessels. LNs are made up of the outer cortex and inner medulla surrounded by a fibrous capsule and mainly contain lymphocytes and B and T cells. T cells reside in the deeper part of the outer cortex, also called the paracortex or T cell zone. This is where T cells and DCs encounter one another. T cells (naïve and central memory) and DCs (primarily mDCs) both express the homing receptor CCR7, which permits trafficking in response to the CCR7 ligands, CCL19, and CCL21, expressed by cells in the LN paracortex.[79] T cell activation is initiated only when T cells encounter a DC presenting their cognate antigen. Increasing the likelihood of a successful encounter, both DCs and T cells are motile and continuously interact with each other in the absence of antigen recognition. DCs are estimated to contact approximately 500 different T cells per hour in the LN.[80] Upon successful encounters, T cell motility decreases, and T cells form stable, long-lasting interactions with DCs. This sustained engagement with DCs stimulates T cells and results in T cell expression of activation markers, effector cytokines, and subsequently clonal expansion. As activated T cells begin proliferating, they regain their motility and exit LNs and return to circulation.[81]

T cell responses can be categorized into three main stages: activation, differentiation, and memory formation. Fully efficient antigen-specific T cell activation requires three distinct signals. Signal 1 is the engagement of the T cell receptor (TCR) with the cognate peptide–MHC complex on APCs. Signal 2 is the co-stimulation and signal 3 is provided by the cytokine milieu. TCRs recognize antigenic peptides only in the context of MHC molecules. TCR binding to pMHC complex is the first trigger for T cell activation and initiates a cascade of downstream signaling, inducing a transcriptional program regulating cellular function. TCR triggering leads to membrane reorganization and formation of the immunological synapse between T cells and APCs. In addition to TCR clusters, co-stimulatory receptors are also recruited to the site. Co-stimulation acts to amplify or counteract the initial activating signals provided by TCR-pMHC interaction.[82] Co-stimulatory molecules are expressed on APC and include the B7.1 (CD80) and B7.2 (CD86), which ligate to CD28 on T cells. Notably, a new member of the B7 family expressed by DCs, B7-DC or programmed death ligand 2 (PD-L2), stimulates naïve T cells highly efficiently.[83] Co-stimulation may also lead to suppression of T cells responses, thereby preventing over-stimulation and autoimmune reactions. For example, binding of B7 ligands to cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) antagonizes CD28 signaling and inhibits T cell activation. Similarly,

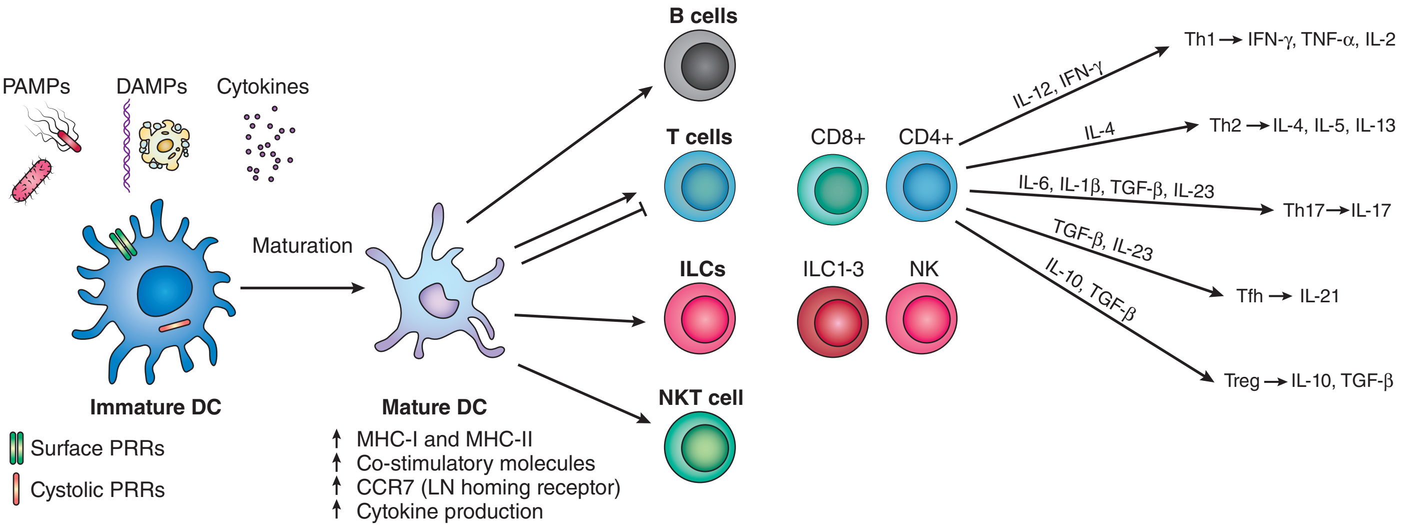

Figure 20.4 DENDRITIC CELLS LINK INNATE AND ADAPTIVE IMMUNITY. DCs sense tissue disturbances and danger signals through their pattern recognition receptors (PRRs) and undergo phenotypical and functional changes, called "maturation" or "activation." Upon maturation, DCs upregulate cell surface expression of MHC and co-stimulatory molecules, as well as cytokine production, pro- or anti-inflammatory. Collectively, these changes impact the DC-mediated differentiation, polarization, and immunomodulatory properties of various immune populations, including B and T cells, innate lymphoid cells (ILCs), and natural killer T cells (NKTs). *DAMP*, Danger-associated molecular pattern; *LN*, lymph node; *PAMP*, pathogen-associated molecular pattern.

engagement of PD-L1 and PD-L2 on DCs with PD-1 on T cells downregulates T cell responses.[84] Importantly, activation of T cells when co-stimulation is absent or suboptimal results in T cell anergy.[85] Co-stimulatory molecules also impact effector T cell differentiation.[84]

Signal 3, provided by cytokines in the microenvironment, determines the skewing of the T cell response such that naïve T cells may terminally differentiate toward different subsets with distinct functions and phenotypes. Classically, these phenotypes are grouped as T-helper cell types Th1 and Th2. IL-12 and IL-4, cytokines produced by DCs, are key determinants of initiation or amplification of Th responses. IL-12 and IFN-γ induce a Th1 phenotype, in which T cells produce IFN-γ, TNF-α, IL-2 and eradicate intracellular pathogens. IL-4 induces a Th2 phenotype with T cells producing IL-4, IL-5, and IL-13, which are important for controlling extracellular parasites.[86] The T cell skewing capacity of DCs depends on several variables. For example, DC expression of T-bet is required for the induction of Th1 responses.[87] DCs activated by human thymic stromal lymphopoietin (TSLP) skew T cells to a Th2 phenotype.[88] The duration of DC activation is also critical for T cell skewing. Prolonged activation causes IL-12 depletion and results in "exhausted DCs," which induce Th2 or nonpolarized T cells.[89] Antigen concentration also determines the direction of T cell skewing, where DCs skew T cells toward Th1 or Th2 phenotypes depending on whether they are presenting high or low amounts of antigen, respectively, which in turn depends on the maturation state of the DCs and consequences of environmental exposure.[90]

The differentiation of naïve T cells into different effector subsets is complex as the inflammatory milieu is comprised of a multitude of cytokines and distinct immune cell subsets. Therefore, a spectrum of T cell phenotypes beyond Th1 and Th2 exists, such as Th9, Th22, Th17, T_{FH} cells, and regulatory T (Treg) cells. DCs can polarize naïve T cells toward these phenotypes as well. For example, iDCs produce IL-6, IL-1β, TGF-β, and IL-23 and efficiently induce TH17 cell polarization.[91] IL-12, together with IL-23 and TGF-β, cytokines produced by activated DCs, induce the differentiation of naïve $CD4^+$ T cells into T_{FH} cells, which secrete IL-21 and regulates B cell responses.[91] Tolerogenic DCs secrete IL-10 and TGF-β and induce the generation of immunosuppressive Tregs.[92]

B Cells

Due to their ability to present antigens and mediate humoral responses, B cells are involved in both innate and adaptive immunity. DCs are important regulators of B cell responses. DCs influence B-cell proliferation, isotype switching, and plasma cell differentiation. DCs and B cells primarily interact in the outer cortex of LNs, as well as in the germinal centers of LNs or spleen. Unlike T cells, B cells recognize antigens in unprocessed native form. DCs possess specialized nondegradative pathways, in which endocytosed antigens are retained intact and recycled to the cell surface without antigen degradation. Therefore, DCs can present internalized antigens in their native state to B cells, engaging the B cell receptor (BCR).[93] Depending on the multivalency of the antigen triggering BCR and the engagement of co-stimulatory molecules, B cells may activate without needing further help. However, if the triggering antigens are of low valency, in order to activate, B cells require help from $CD4^+$ T cells, mainly for the engagement of CD40 by CD40L present on T cells. B cell activation can further be augmented by tumor-necrosis factor (TNF)-family ligands produced by DCs, such as B cell activating factor (BAFF) and APRIL.[94] Once activated, B cells begin to clonally expand and form germinal centers, where B cells undergo isotype switching. DCs may influence this process by mediating CD40-independent isotype switching through BAFF and APRIL.[95] Following these events, B cells differentiate into short-lived plasma cells or memory B cells. IFN-α and IL-6, primarily produced by pDCs, also play a role in inducing plasma cell differentiation.[28] Furthermore, follicular DCs, which are present in germinal centers, participate in the maintenance of B cell memory by providing survival signals.[96]

Innate Lymphoid Cells

Innate lymphoid cells (ILCs) are lymphocytes that lack uniquely rearranged antigen receptors such as those displayed by T and B cells. ILCs comprise three non-cytotoxic cell subsets, namely ILC1, ILC2, ILC3, and a cytotoxic NK cell subset. Due to their functional similarities, ILCs are considered as innate counterparts of T cells with ILC1s, ILC2s, and ILC3s resembling Th1, Th2, and Th17 cells, respectively, while NK cells resemble cytotoxic $CD8^+$ T cells.[97] The interactions between DCs and ILCs are complex and further underscore the role of DCs in linking innate and adaptive immunity.

DCs can promote the differentiation of ILC subsets. IL-12, IL-23, IL-1β, and RA produced by DCs regulate dynamic and reversible differentiation between ILC1 and ILC3 subsets.[98] DCs' ability to produce RA directly improves ILC3 activity by upregulating RORγt and IL-22 expression.[99] RA also controls tissue localization of ILCs by altering ILCs' expression of homing receptors, resulting in a migration of ILCs from lymphoid tissues to the gut.[100] ILCs can also regulate DCs. For example, RA production by DCs may be induced by ILC2-derived IL-13 and GM-CSF.[101] ILC2-derived IL-13 also controls the migration of activated lung DCs into draining LNs, inducing Th2 skewing of CD4 T cells.[102] Finally, ILC3s activate DCs through the expression of membrane-bound lymphotoxin, thereby promoting T cell responses, and in return DCs improve ILC functions, suggesting feedback loops between ILCs, T cells, and DCs.[103]

The crosstalk between DCs and NK cells impacts NK cell activation and cytolytic activity, as well as the maturation state of DCs. NK cells and DCs can form an immune synapse, potentially helping directional and confined secretion of cytokines as well as facilitating receptor–ligand interactions on one another. Activated NK cells contribute to DC maturation through TNF-α and IFN-γ secretion. In turn, activated DCs secrete IL-12, IL-18, IL-15, and IFN-α/β, which enhance the IFN-γ secretion, proliferation, and cytotoxicity of NK cells. In some conditions, NK cells can lyse imDCs through NKp30, although mDCs are protected from cytolysis. This might represent a form of "cellular editing" whereby immature and tolerogenic DCs are cleared by NK cells during an ongoing immune response.[104] The interaction between NK cells and DC is likely to take place early during an ongoing immune response. This allows DC to exploit the ability of NK cells to kill tumor or infected cells and to cross-present this material to T cells, suggesting DCs and NK cells play complementary roles in regulating T cell responses.[105]

Other Elements of the Immune System

DCs have proven to be quite versatile in their ability to interact with various constituents of the immune system. For example, they can activate NKT cells by the presentation of the synthetic ligand α-galactosyl ceramide on CD1, inducing the production of cytokines, such as IFN-γ, and resistance to tumors.[106] CD1-restricted γδ T cells, which respond to microbial antigens from *Mycobacterium tuberculosis* and other organisms, induce maturation of resting DC, and induce IL-12 production. This pathway and the IFN-γ secretion by activated γδ T cells provide the immune system with a source of activated APCs, which can polarize Th1 responses.[106]

In conclusion, the influence of DCs on other cell types of the immune system is broad and integral for the regulation of immunity. Future studies will further determine the roles of the interplay between DCs and the myriad of other immune cells and inform the design of novel therapies to better remedy immunopathology.

DENDRITIC CELLS IN DISEASE

Dendritic Cells and Autoimmunity

DCs play a pivotal role in the balance between immunity and tolerance. DCs are important in the induction of both central and peripheral tolerance. In the former, DCs play a role in the deletion of autoreactive T cells in the thymus. In the latter, DCs in their steady state induce T cell deletion, energy, or generation of regulatory T cells, which interfere with the IL-2 production and proliferation of effector T cells against self. Peripheral tolerance is critical as they limit harmful immune responses to antigens that may not have been available during thymic selection, as well as limiting autoreactive T cells that may have escaped central tolerance.[107] DCs induce peripheral tolerance via a variety of mechanisms, including the activation status of DCs such that resting DCs, in the absence of stimulatory signals necessary for their maturation, can induce robust T cell tolerance against immunodominant antigens.[108,109] These tolerogenic effects of DCs may be mediated through the engagement of inhibitory TCRs, such as PD-1 and CTLA-4, which act synergistically.[110] Additionally, tolerogenic DCs can produce immunosuppressive factors such as indoleamine 2, 3-dioxygenase (IDO), as well as IL-10, TGF-β, IL-35, which induce Tregs and inhibit effector T cell functions.[111] Dysregulation of mechanisms orchestrating tolerance induction by DCs leads to autoimmune diseases. Some of these autoimmune diseases are detailed as follows.

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease affecting multiple organ systems. SLE results from a dysregulated immune system, in which $CD4^+$ T cell and B cell tolerance is impaired, leading to high levels of circulating autoreactive antibodies, in particular against nuclear material.[112] Dysregulation of DCs, including alterations in subset frequency and localization, overactivation of cDCs and pDCs, and functional defects in DCs, is associated with the pathogenesis of SLE. DCs from SLE patients exhibit altered CD40, CD86, Fcγ receptor, and PD-L1 expression.[113–116] Activated cDCs may promote lupus pathogenesis by presenting RNA-associated proteins and chromatin to self-reactive T cells.[117] Abnormalities associated with pDC-derived type I IFN, due to for example persistent stimulation of TLR7 and TLR9 by endogenous nucleic acids, also contribute to the autoimmune responses in SLE.[118–121] Furthermore, DCs may also enhance B cell function and antinuclear autoantibody production.[121–124]

Another autoimmune disease that is associated with increased type I IFN activity is Aicardi–Goutières syndrome (AGS). AGS is an inflammatory encephalopathy that clinically mimics a congenital viral infection despite the absence of virus. AGS is caused by the mutations of several genes involved in nucleic acid metabolism.[125] These mutations may lead to the accumulation of endogenous nucleic acid products, which are then sensed by pDCs, upregulating type I IFN production that is associated with AGS pathogenesis.[126]

Rheumatoid arthritis (RA) is a common chronic autoimmune disease that causes joint pain and its pathogenesis is strongly associated with autoreactive $CD4^+$ T cell functions. Accumulating evidence supports DCs' involvement in RA pathogenesis. Both myeloid and pDCs are found at elevated numbers in the synovial fluid surrounding the joints of RA patients, where they produce pro-inflammatory molecules and contribute to joint inflammation. Although the exact mechanisms through which DCs contribute RA initiation and progression are not fully appreciated, DCs are shown to present MHC class II-restricted self-antigens and induce autoreactive $CD4^+$ T cells, which propagate RA.[127–129]

DCs are involved in the pathogenesis of other autoimmune diseases as well, including multiple sclerosis, type I diabetes, inflammatory bowel disease, and idiopathic inflammatory myopathies.[130] Overall, DCs' role in the development of autoimmune diseases is mediated either via direct activation of self-reactive T or B cells or indirectly by creating a pro-inflammatory environment that interrupts the maintenance of tolerance against self-antigens. When considering treatment approaches for these autoimmune diseases, there is a need to identify and define the balance between regulatory and pathogenic DC roles.

Dendritic Cells and Immunodeficiency

Immunodeficiency disorders can be congenital or acquired and involve an impaired immune system, including DC deficiency or dysfunction. Such diseases have been instrumental in demonstrating the nonredundant in vivo functions of DCs. Congenital immunodeficiencies, also called primary immunodeficiency disorders, are genetic disorders usually present at birth. Mutations in key regulators of DC development and differentiation pathways lead to DC deficiency syndromes, such as mutations in *GATA2*, *IRF8* and *IKZF1* genes. These mutations may result in an absolute deficiency of DCs or a reduction in their numbers. Some DC deficiency syndromes also cause DC dysfunction either through cell-intrinsic effects or by disrupting DC crosstalk with other cells. People with DC deficiencies suffer from increased susceptibility to bacterial, fungal, and viral infections, as well as cancer.[131]

Dendritic Cells and Pathogens

DC deficiency syndromes unequivocally demonstrated the nonredundant roles of DCs in mounting the appropriate antimicrobial immune response in infections. Therefore, pathogens have evolved different mechanisms to inhibit DC functions, allowing them to escape from immune recognition and persist in the host. The mechanisms employed by pathogens to inhibit DC functions can be broadly categorized as downregulation of antigen presentation machinery, impairment of microbial sensing, prevention of DC maturation, and induction of immunosuppressive cytokine production. Some examples of how pathogens modulate DC functions are detailed as follows.

Immunodeficiency syndromes can be acquired, which develop later in life through exposure to a causing agent. One example is the acquired immunodeficiency syndrome (AIDS) caused by the human immunodeficiency virus (HIV) infecting $CD4^+$ T cells. As HIV infection occurs through mucosal areas that are rich in DCs, LCs, and imDCs at submucosa encounter and capture the virus early in the infection. HIV encounter may activate imDCs and lead to their migration to LNs, where they can induce antiviral immune responses. pDCs, especially, in response to HIV secrete high levels of type I IFN, which potently inhibits HIV replication.[132] However, HIV can downregulate the expression of co-stimulatory molecules and MHC molecules, which might diminish the efficacy of antiviral T cell induction.[133–135] DCs may be also susceptible to HIV infection, though much less effectively than $CD4^+$ T cells. The expression of multiple restriction factors in DCs that can block HIV replication renders the productive infection of DCs inefficient.[132] However, DCs may still contribute to HIV spread into $CD4^+$ T cells by hosting the virus and enabling its long-term transmission. Additionally, intracellular HIV might be protected from degradation within DCs and may be trafficked to DC-T synapse or released to extracellular milieu by exosomes, thereby mediating HIV transmission to T cells.[136,137] HIV may also be trapped on the cell surface of follicular DCs and transmitted to T cells through the formation of infectious synapses. DC-SIGN plays a key role in the formation of infectious synapses, in addition to its role as a receptor enabling HIV entry into DCs.[138] Like HIV, both Ebola and Dengue virus also use DC-SIGN to enter DCs.[139,140]

Human cytomegalovirus (HCMV), also called beta-herpes virus 5, infects the majority of the world population and establishes lifelong infection. Although commonly asymptomatic in healthy individuals, HCMV infection can be fatal in immunocompromised people. HCMV can non-productively infect DCs and modulate DC function. HCMV downregulates MHC class I and II expression in DCs by downregulating ERAP1, inhibiting MHC-II transcription, degrading MHC-II, and interfering with MHC-II and invariant chain interaction. MHC downregulation in DCs enables HCMV escape from T cell recognition. Notably, HCMV can also inhibit NK cell function and avoid NK cell-mediated lysis in absence of MHC-I molecules.[141] HCMV can mediate its inhibitory effects on DCs and T cells also by inducing immunosuppressive cytokine production, such as IL-10. HCMV can encode a functionally active viral IL-10 homolog, as well as induce DCs to produce IL-10.[142]

DENDRITIC CELLS AND CANCERS

The DC-mediated events leading to a successful antitumor immune response can be summarized as (1) DC access to tumor antigens in the tumor microenvironment (TME); (2) DC activation in response to DAMPs in the TME; (3) tumor antigen uptake by DCs; (4) DC migration to LNs; (5) cross-presentation of tumor antigens to T cells, activating tumor-specific $CD8^+$ cytotoxic T cells (CTL); (6) trafficking of CTL to TME; and (7) tumor cell killing by CTL (Fig. 20.5).[143] As they excel at cross-presentation, the cDC1 subset of DCs is particularly important for eliciting antitumor CTL responses.[17] Notably, $CD4^+$ T cells also play a crucial role in establishing antitumor immunity by enhancing the efficacy of CTL and directing sustained antitumor immune responses.[144,145] Moreover, tumor-specific $CD4^+$ T cells may also directly exert cytotoxic function.[146–148]

Increased susceptibility to cancer in people with DC deficiencies, as well as aggravated tumorigenesis observed in Batf3 knockout mice, which lack cross-presenting cDC1s, demonstrate the importance of DCs in mediating antitumor immunity.[131,149,150] The strong correlation between the abundance of tumor-infiltrating cDC1s and clinical outcome in cancer patients further corroborates these observations.[151] Therefore, inhibition of cDC1s is beneficial for tumor progression.

Tumors have evolved to escape immune responses through various mechanisms, including abrogating DC function. Tumor cells establish a highly immunosuppressive TME that perturbs DC recruitment, differentiation, survival, function, and exploits the tolerogenic capacity of DCs (see Fig. 20.5).[152] Tumor-derived factors can limit cDC1 recruitment to the tumor site by modulating DC-attractant chemokine production. For example, active β-catenin in tumors reduces CCL4 production.[153] Similarly, prostaglandin E_2 (PGE_2) impairs CCL5 and XCL1 production by NK cells.[154] Tumors can also inhibit cDC differentiation and survival through the downregulation of NK cell-derived Flt3L by secreting vascular endothelial growth factor (VEGF).[155,156] Likewise, PGE_2 can inhibit iDC differentiation, as well as cDC maturation and survival.[157] Moreover, IL-6 in the TME, produced by both tumor and immune cells, also inhibits cDC and iDC differentiation.[157] Tumors inhibit DC activation also by impairing sensing of DAMPs. For example, tumor-infiltrating cDCs upregulate TIM-3 expression, which interacts with an alarmin (HMGB1) and blocks nucleic acid recruitment into DC endosomes.[158] CD47 expression by tumors also impedes tumor DNA sensing by cDCs.[159] DC migration to LNs, a key step for the generation of antitumor T cell responses, also can be restrained by tumor-derived liver X receptor (LXRα) ligands.[160] Another mechanism employed by tumors to bypass DC-mediated immunity is to alter their antigen profile. Tumors can post-translationally modify their antigens, such as MUC1 and HER2 glycosylation, and render DCs unable to process these antigens by blocking antigen transport from early endosomes to downstream compartments.[161]

Tumors can also affect the cytokine secretion profile of DCs, polarizing them to a more tolerogenic state and perpetuating an immunosuppressive TME. For example, Versican, a tumor-derived TLR2 ligand, induces IL-10, IL-6, and their receptor expression in DCs.[162] IL-6 can downregulate MHC-II and CCR7.[163,164] IL-10 secretion, by DCs and macrophages within TME, can abolish IL-12 production by DCs.[165] IL-6 and IL-10, among other TME factors such as VEGF, also trigger signal transducer and activator of transcription 3 (STAT3) signaling, which is hyperactivated in cancer and contribute to tumor growth and immunosuppression in TME.[166] STAT3 signaling can upregulate the expression of immunoregulatory molecules in DCs, such as programmed cell death ligand 1 (PD-L1), which binds to the inhibitory receptor PD-1 on T cells.[167] Moreover, STAT3 activation can inhibit DC maturation, as well as DC expression of MHC-II, co-stimulatory molecules, and IL-12.[168] STAT3 signaling also plays a key role in the accumulation of an immature myeloid cell population with immunosuppressive functions, so called myeloid-derived suppressor cells (MDSCs), at the TME. MDSCs mediate their immunosuppressive effects through a myriad of mechanisms, including the activities of arginase-1 (ARG-1) and inducible nitric oxide synthase (NOS2), as well as the secretion of immunoregulatory cytokines, such as IL-10 and TGF-β.[169] In addition to directly inhibiting T cells, MDSCs can also impair the differentiation, maturation, and antigen presentation ability of DCs.[169] For example, TGF-β can induce epigenetic modifications that impair DC function and differentiation.[170]

Another immune escape mechanism utilized by tumors is skewing T cell differentiation. IL-10 and TGF-β induce Tregs, which inhibit effector $CD8^+$ and $CD4^+$ T cell functions.[171] Tregs may also modulate cDC2 function and migration, leading to inhibition of cDC2-mediated proinflammatory Th1 differentiation of antitumoral $CD4^+$ T cells.[172] Additionally, tumors overexpress matrix metalloproteinase-2 (MMP-2). MMP-2, through its binding to TLR2 on DCs, conditions DCs to produce low levels of IL-12 and to express OX40-L, thereby biasing antitumor $CD4^+$ T cells toward Th2 differentiation associated with anti-inflammatory responses.[173,174]

Finally, TME is highly hypoxic, deprived of adequate oxygen. One underlying mechanism for tumor-promoting effects of hypoxia is its contribution to immunosuppression, such as by inducing Tregs and MDSCs.[175] Hypoxia also mediates metabolic reprogramming

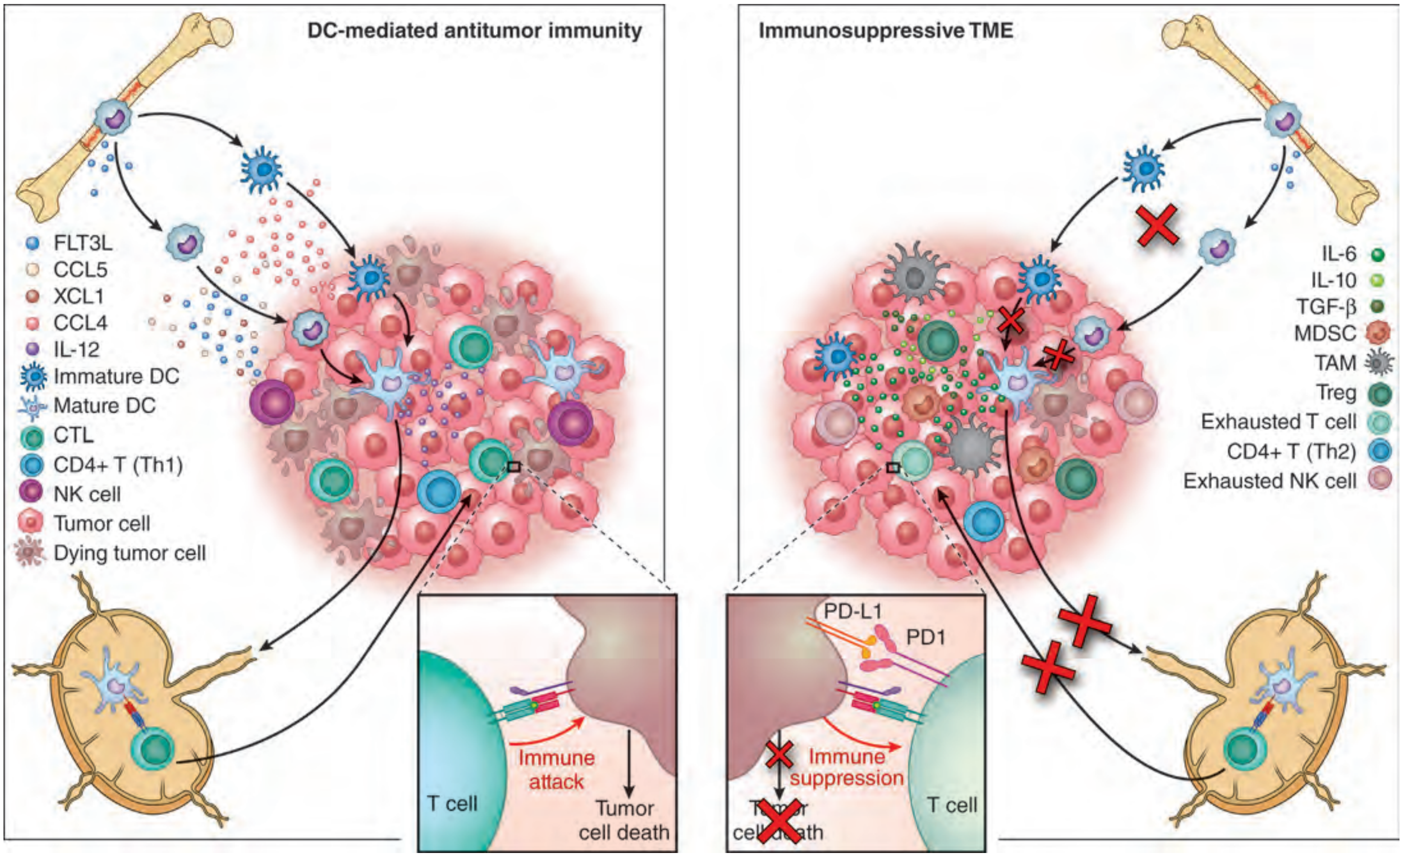

Figure 20.5 IMMUNE ESCAPE MECHANISMS EXPLOITED BY TUMORS. Summary of DC-mediated events leading to a successful antitumor immune response *(left)*: DCs are recruited to the tumor microenvironment (TME) in response to CCL5 and XCL1, produced by natural killer (NK) cells, and CCL4, produced by tumor cells. In the TME, DCs are activated in response to danger-associated molecular patterns (DAMPs) and uptake tumor antigen uptakes. Subsequently, DCs migrate to lymph nodes (LNs), where they cross-present tumor antigens to T cells, activating tumor-specific $CD8^+$ cytotoxic T cells (CTL). CTLs traffic back to the TME and kill tumor cells. However, tumors have evolved to escape immune responses through various mechanisms *(right)*, including inhibition of DC recruitment, differentiation, survival, function, and exploiting the tolerogenic capacity of DCs. Tumor-derived β-catenin and prostaglandin E_2 (PGE_2) block DC infiltration by inhibiting chemokine secretion by tumor and NK cells, respectively. Vascular endothelial growth factor (VEGF) secreted by tumors downregulates NK cell-derived Flt3L, thereby inhibiting DC differentiation and survival. Tumors also impair sensing of DAMPs by DCs and DC migration into LNs. Tumors can also affect the cytokine secretion profile of DCs, polarizing them to a more tolerogenic state, leading to the accumulation of immunoregulatory cells, such as myeloid-derived suppressor cells (MDSCs), tumor-associated macrophages (TAMs), and T regulatory cells (Tregs), in the TME, as well as the induction of checkpoint molecules and their ligand expressions, such as PD-1 on T cells and PD-L1 on tumor cells or myeloid cells.

in immune cells, including DCs. Hypoxia enhances the production of adenosine and IDO by DCs, whose activities can inhibit T cells and NK cells.[176,177] Hypoxia also causes ER stress, which can reduce DC maturation.[178] Moreover, ER stress leads to abnormal lipid accumulation in DCs, which inhibits the translocation of peptide-loaded MHC-I molecules to the cell surface, thereby blocking antigen cross-presentation.[179,180]

IMMUNOTHERAPEUTIC STRATEGIES AND CLINICAL TRIALS

The immune system can distinguish self from non-self and eliminate intruding or transformed material from the body. The advancement in the understanding of innate and adaptive immune responses and their regulation has enabled targeted strategies mobilizing the immune system to combat immunopathology. In recent years, immunotherapy has revolutionized the treatment of diseases, in particular cancer. An important type of immunotherapy is DC vaccination (Fig. 20.6). Numerous clinical trials conducted over the last two decades have established the safety and feasibility of DC vaccines aimed to generate immune responses against infectious pathogens, for example, HIV, and various tumor antigens.[181] Despite eliciting and strengthening antigen-specific immune responses, DC vaccination as monotherapy yields suboptimal clinical outcome. For example, the use of Sipuleucel-T, the first DC-based cancer vaccine approved by the US Food and Drug Administration (FDA), for the treatment of metastatic castration-resistant prostate cancer prolonged median survival time by 4.1 months compared to the placebo-treated patients.[182] In general, objective response rates with DC-based cancer vaccines rarely exceed 15%.[183] Similarly, according to a recent meta-analysis of 12 clinical trials, the overall success rate of DC vaccination for the treatment of HIV, defined as partial or at least transient viral load decrease, was estimated to be 38.2%.[184] The suboptimal clinical performance of DC vaccines highlights the need to understand the DC biology better and improve the design of therapeutic DC-based strategies.

DCs comprise a small fraction of blood cells. Therefore, the generation of sufficient DC numbers for vaccination strategies may be challenging. Various ex vivo protocols have been developed to generate patient-derived autologous DC subsets, for example, moDCs, cDCs, or pDCs, from distinct sources, such as peripheral blood monocytes or $CD34^+$ precursor cells mobilized from the bone marrow. Isolation techniques used to obtain the source population, as well as the culture method utilized to expand DCs, influence the phenotype, function, and potency of ex vivo generated DCs.[13,185,186] Due to the ease of ex vivo expansion protocols and their availability, moDCs have been

Figure 20.6 DENDRITIC CELL-BASED CANCER VACCINES. Summary of some of the DC-based cancer vaccination strategies being used in clinical trials to induce antitumor adaptive immune responses. Tumor antigens can be loaded onto ex vivo generated DCs and administered to the patients alone or in conjunction with adjuvants. An alternative to ex vivo production of DC vaccines is in situ vaccination, in which the vaccine is generated in vivo. Combining DC-based cancer vaccines with different immunomodulatory treatments might provide therapeutic synergism. *Flt3L*, Fms-like tyrosine kinase receptor 3 ligand; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *mRNA*, messenger RNA; *PGE2*, prostaglandin E2; *Poly-ICLC*, polyinosinic-polycytidylic acid – poly-L-lysine carboxymethylcellulose; *TLR*, Toll-like receptor.

most frequently used for the preparation of DC vaccines.[187] However, as each DC subset is unique in their antigen presentation capacity and role in disease settings, the adaption of ex vivo culture systems that allow generation and expansion of different DC subsets (cDC1, cDC2, and pDC)[13] to clinical settings will be key to improve the efficacy of DC vaccines. Several studies evaluating the efficacy of pDC and cDC-based cancer vaccines are already underway.[188–191]

Antigen selection and antigen delivery are two key factors that contribute to the success of DC-based therapies. DC vaccines are intended to promote strong antigen-specific adaptive immunity. Therefore, the immunogenic potential of the targeted antigens impacts the magnitude of elicited immune responses. To date, most DC vaccines are prepared by loading autologous DCs with microbial or tumor antigens ex vivo prior to reinfusion into patients. Various antigen sources can be utilized to load DCs ex vivo: (1) synthetic peptides[192–194]; (2) whole tumor lysates[195,196] (e.g., NCT03803397 and NCT03990493 by PrimeVax); (3) DC-tumor cell fusions, hybrid cells that act as DCs and express complete tumor antigens[197–199]; (4) electroporation with mRNA encoding antigens[200]; and (5) transduction with viral vectors encoding antigens.[201] An alternative to ex vivo production of DC vaccines is in situ vaccination, in which the vaccine is generated in vivo.[202] This strategy eliminates the need for ex vivo cell manipulation, thereby simplifying the vaccine production pipelines. Agents utilized to form in situ DC vaccines include (1) antibodies binding to DC-specific cell surface molecules, such as Clec9A, Clec12A, Mannose receptor, DEC-205 and CD40 (e.g., NCT03358719, NCT02166905, NCT02376699, NCT02482168, NCT00648102, NCT00709462, and NCT01103635) that can mediate antigen delivery to DCs[203]; (2) viral vectors encoding antigens[204]; (3) oncolytic viruses, which induce tumor cell death, thereby releasing tumor antigens[205]; (4) nanoparticles[206,207]; (5) DC-activating agents[208]; (6) modified RNA or DNA vaccines (NCT02410733)[209]; and (7) GM-CSF-transduced tumor cells (GVAX platform).[210–213] Other platforms that combine ex vivo and in situ DC-based vaccination approaches have also been developed and tested in mouse models, such as the extracellular vesicle internalizing receptor (EVIR) platform, in which DCs are transduced with a chimeric receptor encoding lentivirus ex vivo that enables the selective uptake of tumor-derived EV in vivo.[214] Talimogene laherparepvec (T-VEC), a modified herpes simplex virus, is a first-in-class FDA-approved oncolytic in situ vaccine. T-VEC selectively replicates in tumor cells and lyses them, which release viral progeny and tumor antigens. Additionally, T-VEC expresses GM-CSF and promotes DC function.[215] FDA approved the use of T-VEC in patients with unresectable melanoma after a 16.3% durable response rate in patients receiving intralesional T-VEC versus 2.1% in patients receiving subcutaneous GM-CSF, as well as a 4.4-months prolonged median survival time in the T-VEC group.[216]

Another important factor impacting the potency of DC-based vaccinations is the method for DC activation. Various strategies mentioned previously for antigen loading to DCs can also be utilized for introducing DC-activating agents. DCs may be activated by TLR ligands, such as TLR3 agonist Poly-ICLC, TLR4 agonist LPS, TLR7 agonist imiquimod, TLR7 and TLR8 agonist resiquimod, and TLR9 agonist CpG DNA.[217] Pro-inflammatory cytokines, such as IFN-I, IL-1β, IL-6, TNF, and PGE_2, can also be used to activate DCs.[218] In addition, DCs can be engineered to express multiple immunostimulatory molecules. For example, the Trimix DCs express constitutively active TLR-4, as well as CD40-L and CD70.[219] Alternatively, expression of inhibitory molecules, such as PD-L1 and PD-L2, by DCs can be silenced, for example, by using siRNA (NCT02528682).[220] Intratumoral (IT) injection of DC-activating agents can lead to in situ activation of DCs. For example, IT administration of TLR9 agonist

CpG oligonucleotide PF-3512676, together with low-dose radiation, in patients with low-grade B-cell lymphoma induced tumor-specific $CD8^+$ T cells and led to complete or partial responses in a subset of patients.[221] Other immune modulators such as Poly-ICLC[222,223] and STING agonists[224] have also been tested as inducers of in situ DC activation. Moreover, stimulating local inflammation, e.g., by administering potent recall antigens[225] or Flt3L[208], is another strategy to enhance the efficacy of DCs. To enhance the elicited immunity, multiple agents can be incorporated into the design of the DC vaccine. For example, a recent phase II trial tested a regimen of Flt3L treatment together with Poly-ICLC and a vaccine comprising anti-DEC-205-NY-ESO-1 in high-risk melanoma patients, where Flt3L administration was randomized. Findings demonstrated that the addition of Flt3L enhanced the immunogenicity of the DC vaccine and induced potent and durable immune responses.[226]

The superior efficacy and clinical relevance of combination therapies over monotherapies, by therapeutic synergism while retaining safety profiles, have been demonstrated in many contexts.[227] Accordingly, to unleash the full power of DC-based therapies, combination strategies with different immunomodulatory treatments, for example, chemotherapy, radiotherapy, and checkpoint blockade, have been studied.[228] In addition to eliminating malignant calls and lowering tumor burden, chemotherapy, and radiotherapy-triggered tumor cell death releases tumor antigens and induces exposure of immunogenic molecules on tumor cells, which facilitate DC antigen uptake and activation.[228] Chemotherapy drugs can induce other immunogenic signals that further stimulate DCs. For example, taxane-induced release of cellular ATP potentiates inflammasome activation and IL-1β release, and cyclophosphamide-induced release of tumor nucleic acids can lead to type I IFN secretion.[229] Finally, chemotherapy can deplete immunosuppressive cells at the TME, rendering TME more sensitive to DC vaccine-induced antitumor T cell activity.[228] Checkpoint inhibition (ICI) can also improve the efficacy of DC-based therapies, both by reinvigorating DC-therapy-induced T cells (e.g., anti-PD-1, anti-CTLA-4) and blocking inhibitory molecules expressed by DCs (e.g., anti-PD-L1). In fact, several studies have indicated an enhanced efficacy of DC-therapy upon combination with ICI.[230]

Finally, other factors also influence the success of DC-based treatments, such as the route, dose, and schedule of vaccine administration, as well as the timing of vaccination. Although most DC vaccination trials to date have been conducted in patients with advanced disease, DC-therapy is likely to be most effective in patients with low tumor burden, as early neoadjuvant studies suggest (NCT01431196, NCT03387553).[231–233] Future controlled studies integrating these key components will improve the efficacy of DC-based therapies both in cancer and infectious disease settings.

FUTURE DIRECTIONS

As they bridge the innate and adaptive immunity, DCs are key targets for clinical applications in cancer, transplantation, and chronic infections. A deeper understanding of DC biology will improve the efficacy of current DC-based therapies and develop effective novel methodologies. Indeed, promising approaches enhancing DC recruitment and activity, which increase response rates, in various disease settings are already underway.

CHAPTER 21

NATURAL KILLER CELL IMMUNITY AND THERAPY

William E. Carson III

Natural killer (NK) cells are large, granular lymphocytes that comprise about 10% to 15% of the circulating peripheral blood lymphoctyes.[1–3] These unique cells were first characterized by their ability to lyse targets independently of activating or initiating stimuli.[4] NK cells are a critical cellular component of the innate immune system that have the ability to target and lyse malignant and virally infected cells. In addition, NK cells secrete cytokines that help to organize and shape the innate and adaptive immune response to infectious insults and malignant transformation. There is increased interest in NK cells as therapeutic agents as discoveries in the laboratory and the clinic have led to a better understanding of the important role played by NK cells in molding the early immune response.[5] NK cells play a key role in maintaining host defense, as illustrated by human NK cell deficiency syndromes which carry increased susceptibility to overwhelming viral, intracellular, and atypical mycobacterial infections.[6] Further, murine models of NK cell deficiency are characterized by a distinct susceptibility to development of cancer, and reduced NK cell activity in humans is associated with a higher risk for developing malignancy.[7–9] This chapter provides a review of the current understanding of NK cell biology, the role of NK cells in human disease, and the recent clinical applications of NK cells to the therapy of cancer.

NATURAL KILLER CELL FUNDAMENTAL BIOLOGY

NK cells are critical cellular components of the innate immune response and are particularly important in the early control of viral infections and the elimination of malignant cells. NK cells express a number of receptors, both activating and inhibitory, that enable them to identify cellular targets that are not part of the host's normal tissues. The overall balance between activating signals and the absence of inhibitory signals will lead to NK cell activation and the initiation of effector cell programs. NK cells also constitutively express a number of cytokine receptors including receptors for interleukin (IL)-2, IL-10, IL-12, IL-15, IL-18, and IL-21. The ability of NK cells to sense very low levels of these cytokines allows them to be intimately attuned to the current status of the immune microenvironment. And unlike T cells, NK cells do not require antigenic stimulation in order for cytokine receptor expression to occur. For example, resting NK cells express high levels of a functional IL-2 receptor and are able to rapidly respond to this cytokine. NK cells will embark upon the immediate cytolytic destruction of cells that do not display the appropriate "self molecules"; however, they also produce large amounts of multiple cytokines with potent effects on other immune compartments such as interferon-gamma (IFN-γ), tumor necrosis factor (TNF)-α, and granulocyte–macrophage colony-stimulating factor (GM-CSF). Notably, IFN-γ is described as the prototypical macrophage activating factor, and NK cells are known to interact with and facilitate the function of this cellular compartment as well as dendritic cells and T cells. Under the appropriate conditions, NK cells are also potent producers of chemokines such as IL-8, macrophage inflammatory protein-1-alpha (MIP-1α), and RANTES (regulated upon activation, normal T Cell expressed and presumably secreted) that have the ability to attract T cells and macrophages to sites of immunologic activity. NK cell mobilization is aided by the expression of chemokine receptors that direct their trafficking during development and differentiation and promote their recruitment to sites where an immune response is developing. NK cell adherence to the vascular endothelium is the first step in their deployment to sites of infection or malignancy and this process is facilitated via their expression of abundant levels of multiple adhesion molecules. NK cell expression of cellular adhesion molecules also promotes the formation of conjugates between NK cells and susceptible target cells. These characteristics of the NK cell compartment are indicative of a complex immune cell type with potent effector functions.[1–3]

Natural Killer Cell Subsets

NK cells are phenotypically recognized by surface expression of CD56 (also called *neural cell adhesion molecule*) and the absence of the T-cell receptor as evidenced by lack of CD3 expression.[10,11] Two functional subsets of NK cells may be discriminated from one another based on the intensity of CD56 surface expression, the so-called CD56^{bright} and CD56^{dim} subsets. CD56^{dim} NK cells comprise 85% to 90% of the NK cells in the peripheral circulation and are generally considered to be potent mediators of cytotoxicity. About 10% to 15% of NK cells in the blood are CD56^{bright}, and upon activation, this subset is capable of robust cytokine and chemokine production.[12] Fig. 21.1 graphically depicts these NK subsets, and Table 21.1 summarizes major surface antigens associated with each NK cell subset. While the use of CD56 expression is useful in understanding NK cell biology and function, it is also apparent that the differential cytolytic function and cytokine output of the bright and dim subsets is not absolute and can be altered (and even reversed) by specific environmental cues.

CD56^{dim} Natural Killer Cells

CD56^{dim} NK cells are strongly cytolytic and are able to kill infected as well as tumor cell targets without prior sensitization.[13] They constitutively express the interleukin-2/15 (IL-2/IL-15) receptor (R) β- and common γ-receptor chains, which together form a receptor complex through which cells may respond to stimulation following exposure to either IL-2 or IL-15.[14,15] CD56^{dim} NK cells can lyse tumor cell targets through at least three distinct mechanisms. First, they can execute cytotoxicity through the exocytosis of lytic granules containing the pore-forming protein perforin and proteases called granzymes (e.g., granzyme B or GrzB) which initiate an apoptotic program via cleavage of specific protein substrates. Second, cytotoxicity can be mediated through NK cell expression of Fas ligand (CD95L) and TNF-related apoptosis-inducing ligand (TRAIL) which interact with their respective receptors CD95/Fas and TRAIL-R1 and -R2 on the target cell surface.[16] This binding event leads to recruitment of the Fas-associated protein with death domain (FADD), recruitment and activation of procaspase 8 and 10, and the initiation of a caspase cascade that results in target cell apoptosis. This process is associated with NK cell production of cytokines, IFN-γ, TNF-α, and GM-CSF.[17] Third, CD56^{dim} NK cells can mediate antibody-dependent cytotoxicity (ADCC) via the high-level surface expression of CD16 (FcγRIIIA), a low-affinity receptor for IgG which mediates a lytic program against antibody-coated target cells.[18] Compared with CD56^{bright} NK cells, freshly isolated, unstimulated CD56^{dim} NK cells have intrinsically greater cytotoxicity in vitro against NK-sensitive tumor targets such as the well-studied K562 chronic myelogenous

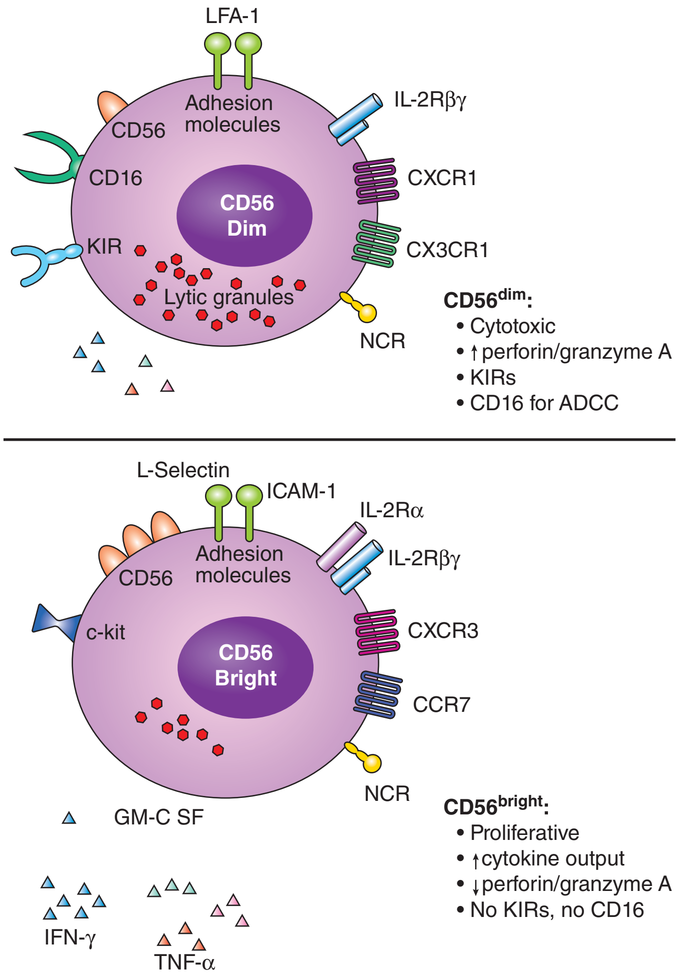

Figure 21.1 SIMPLIFIED REPRESENTATION OF NATURAL KILLER CELL SUBSETS. leukemia cell line,[19] and they exhibit relatively high surface density expression of killer-cell immunoglobulin-like receptors (KIRs), a family of polymorphic activating and inhibitory receptors that are critically important in regulating NK cell surveillance of host tissues for cells with "altered self" (see below).[20]

CD56^{bright} Natural Killer Cells

CD56^{bright} NK cells appear to play an immunoregulatory role in the innate immune response. CD56^{bright} NK produce multiple cytokines and chemokines, have a relatively high proliferative capacity, reside primarily in the parafollicular T cell–rich region of secondary lymphoid tissue (SLT), and have modest levels of cytolytic granules, low expression of KIR and FcγRIII (see Table 21.1).[13] CD56^{bright} NK cells are unique among cytotoxic effector cells in their constitutive expression of the heterotrimeric high-affinity IL-2 Rαβγ complex, making them responsive to picomolar concentrations of IL-2 released by activated T cells in the SLT parafollicular region.[21] As noted, CD56^{bright} NK cells comprise only about 10% of the circulating NK population but predominate almost to the exclusion of the CD56^{dim} NK subset in SLT.[22] This distribution likely results from their selective expression of a number of receptors that assist in homing cells to SLT and retaining them there (e.g., CCR7 and CD62L).[13,23] NK cell precursor expression of the C-type lectin-like surface activating receptor NKp80 correlates with NK cell functional maturity in SLTs. NKp80 may play an important regulatory role during NK maturation in SLTs related to the acquisition of cytotoxic functions and/or cytokine-production.[24]

Chemokine receptor repertoires (and thus migration patterns) are differentially aligned among NK cell sub-populations. Compared to CD56^{dim} NK cells, CD56^{bright} NK cells express higher levels of chemokine (C-X-C motif) receptor 4 (CXCR4) which is the receptor for CXCL12 (also knowns as SDF-1α/β). CXCL12/SDF-1 stimulates NK cell migration and its production by trophoblasts is responsible for maintaining a population of CD56^{bright} NK cells within the decidua of the uterus during pregnancy. The CD 56^{bright} subset is directed to lymph nodes via their expression of CCR7, and they preferentially express CXCR3 which binds the interferon-inducible chemokines CXCL9 (MIG), CXCL10 (IP-10), and CXCL11 (I-TAC). This pattern of chemokine receptor expression, along with the high levels of the adhesion molecule L-Selectin (CD62L), helps to explain the prevalence of CD56^{bright} NK cells in secondary lymphoid tissues. In contrast, CD56^{dim} NK cells uniquely express high levels of receptors specific for inflammatory chemokines such as CXCR1, CXCR2, and CX3CR1.[25] CXCR1 binds IL-8 (CXCL8), the levels of which are increased in the setting of acute viral infections and correlate with disease severity.[26] Fractalkine (CX3CL1), the ligand for CX3CR1, is induced at sites of inflammation and acts as an adhesion protein for cells with CX3CR1 expression, resulting in retention of NK cells on vessel walls. As a member of the seven transmembrane domain G protein-coupled receptor family, CX3CR1 activation leads to NK cell stimulation via calcium mobilization and the initiation of mitogen-activated protein kinase (MAPK) and PI3 kinase signaling.[27] Thus, expression of these chemokine receptors allows NK cells to traffic to local areas of inflammatory response to augment and modify the host immune response. Altered expression of chemokine ligand/receptor pairs can also promote malignant disease. In murine models of multiple myeloma, there is increased bone marrow expression of CXCL9 and CXCL10 which leads to downregulation of CXCR3 on NK cells and reduced migration and retention of NK cells to this site.[28]

Not unexpectedly, NK cell expression of adhesion molecules also differs between the two CD56 subsets. An analysis of CD56^{dim} NK cells reveals that they express CD11a at a high level as compared to the bright subset. CD11a is the α chain of the $\alpha\gamma_L\beta 2$ integrin (also known as leukocyte function associated antigen 1 [LFA-1]. Integrins bind to a wide variety of ligands in the extracellular matrix, on the surface of other cells and also soluble proteins. In contrast, CD56^{bright} NK cells exhibit high-level expression of CD11c. They also express high levels of CD2, CD44, CD49e, CD54, and CD62L as compared to the dim subset. CD44 binds to hyaluronic acid in the extracellular matrix.[12] CD49e belongs to the integrin alpha chain family and associates with CD29 (integrin beta1) to form the VLA-5 receptor which binds to fibronectin and fibrinogen. CD54 is upregulated during activation and strengthens the NK-target during the lytic process. L-selectin (CD62L) is a type-I transmembrane glycoprotein that has been identified as a tethering/rolling receptor. As a result of these differing repertoires of adhesion molecules and chemokine receptors, the migratory properties of NK cells diverge quite significantly. The CD56^{bright} subset migrates preferentially to secondary lymphoid organs whereas CD56^{dim} NK cells are attracted to sites of acute inflammation.[12]

The ability of CD56^{bright} NK cells to produce an abundant variety of cytokines and chemokines compared with the CD56^{dim} subset likely relates more to the differential expression of both negative and positive regulators of cytokine/chemokine production and less to constitutive expression of cytokine-activating receptors. For example, CD56^{bright} NK cells have little or no expression of two negative regulators of cytokine/chemokine production, namely SHIP-1 (Src homology 2 domain-containing inositol 5-phosphatase 1) and HLX (H2.0-like homeobox 1).[29,30] CD56^{dim} NK cells lack constitutive expression of a positive regulator of cytokines called *SET*.[31] Single-cell transcriptomic analyses generally support the use of CD56 as a means of identifying NK cell subsets with mature populations expressing high levels of CXCR1, TIM-3 (inhibitory checkpoint molecule), and ZEB2.[32]

TABLE 21.1 Differential Properties of CD56$^{\text{bright}}$ and CD56$^{\text{dim}}$ Natural Killer Cells

Factor/Molecule[a] (Other Name)	Binding Partner/Function	CD56$^{\text{bright}}$	CD56$^{\text{dim}}$
CD56 (NCAM-1)	NK cell marker	++	+
CD16 (FcγRIIIa)	Binds Fc region of IgG	−(± in some individuals)	++
c-kit (CD117)	Binds stem cell factor (SCF)	+	−
CD57 (Leu-7)	Marker of differentiated NK cells with high cytotoxic/low proliferative potential	−	+
KIR-inhibitory (e.g., KIR2DL, 3DL)	Binds HLA C2 (inhibitory signal)	−	+
KIR-stimulatory (e.g., KIR2DS, 3DS)	Binds HLA C1 (stimulatory signal)	−	+
NKG2A (forms heterodimer w/ C-type lectin CD94)	Binds HLA-E (inhibitory signal)	+	±
NKG2C (heterodimer w/ CD94)	Binds HLA-E (activating signal)	±	±
NKG2D	Activating Binds MICA, MICB, and 6 members of ULBP family	+	+
NKp30	Natural cytotoxicity receptor (NCR) Recognizes N-terminal IgV domain of B7-H6/hemagglutinin (HA) of vaccinia virus	++	+
NKp44	NCR, expressed after NK activation Recognizes HA of influenza and Sendai viruses	±	±
NKp46	NCR Recognizes HA of influenza, vaccinia viruses Upregulated upon cytokine stimulation	++	+
DNAM-1 DNAX accessory molecule-1 (CD226)	Promotes NK cell cytotoxicity and IFN-γ release upon binding to ligands poliovirus receptor (PVR, nectin-like molecule 5, CD155) or herpes entry mediator (B—HVEB, Nectin-2, CD112)	+	++
IL-2R alpha (CD25)	High affinity IL-2 receptor	++	−
IL-2R beta (CD122)	Intermediate affinity IL-2 receptor	++	+
CCR5	Receptor for CCL3, 4, 5 (MIP-1α, MIP-1, RANTES)β	+	+
CCR7	Receptor for CCL19, 21 (MIP-3β, 6Ckine)	++	−
CXCR1	Receptor for CXCL1 (IL-8)	−	++
CXCR2 (IL-8R beta)	Receptor for CXCL8 (IL-8)	+	−
CXCR3	Receptor for CXCL9, 10, 11 (MIG, IP-10, ITAC)	++	±
CXCR4	Receptor for CXCL12 (SDF-1α/β)	±	±
CX3CR1	Receptor for CX3CL1 (fractalkine)	−	+
CD44	Binds hyaluronic acid Enhances NK cell functions via increased Ras, MAPK, and PI3K signals	++	+
CD2	Adhesion molecule Binds to other adhesion molecules (e.g., LFA-3)	+ +	+
L-selectin (CD62L)	Adhesion molecule Binds to CD34, GlyCAM1, MadCAM1	++	±
ICAM-1 (CD54)	Binds to integrins CD11a/CD18, or CD11b/CD18	++	±

TABLE 21.1 **Differential Properties of CD56$^{\text{bright}}$ and CD56$^{\text{dim}}$ Natural Killer Cells—cont'd**

Factor/Molecule[a] (Other Name)	Binding Partner/Function	CD56$^{\text{bright}}$	CD56$^{\text{dim}}$
LFA-1 (CD11a/CD18, αLβ2 integrin)	Binds ICAMs Initiates immune synapse formation and provides activating signals	+	++
Perforin	Pore-forming cytolytic protein found in granules	–	++
Granzyme A	Serine protease induces apoptosis by cleaving/inactivating diverse substrates (e.g., mitochondrial e- transport protein)	+	++
Granzyme B	Serine protease that induces apoptosis by activation of caspases	–	++
Granzyme K	Granzyme K (GrK) and GrA have trypsin-like activity and cleave after basic residues arginine and lysine; GrB cleaves after aspartic acid residues	+	–

[a] Expression levels of the listed molecules may vary across the CD56$^{\text{bright}}$ and CD56$^{\text{dim}}$ NK cell subsets due to donor type and variability, NK cell isolation protocols, flow cytometry gating strategies, antibody reagents being employed, and NK cell activation status.

NATURAL KILLER CELL DEVELOPMENT

NK cells are prototypic, founding members of a population of cells referred to as innate lymphoid cells (ILC).[33] Three populations of ILC have been described based on differential expression of specific transcription factors and cytokine production. NK cells are believed to arise from group 1 ILCs, which are characterized by T-bet and EOMES expression.[34] T-bet and EOMES are T-box transcription factors that serve as master regulators of lymphoid cell differentiation. Acquisition of the IL-15 receptor is likely a first step toward NK cell differentiation from CD34$^+$ hematopoietic stem cells and a subsequent common lymphoid precursor cell. Moreover, IL-15 is required for NK cell development in mice and humans,[35–37] and the NK cell maturation process appears to occur outside the bone marrow.[3,38] In humans, IL-15 has been found to regulate an NK cell signaling pathway that employs the serine-threonine kinase AKT and the transcription factor XBP1s which controls genes belonging to the unfolded protein response family.[39] IL-15 induced accumulation of XBP1s in the NK cell nucleus enables increased T-BET-mediated transcription of the granzyme B gene. XBP1s promotes NK cell cytotoxicity and is critical for IL-15-mediated NK cell survival.

Freud et al. identified a CD34$^{\text{dim}}$CD45RA$^+\alpha_4\beta_7^{\text{bright}}$ cell to be the only CD34$^+$ subset in SLT.[22] Found within the parafollicular T cell–rich region of SLT in the same region as the CD56$^{\text{bright}}$ NK cell, the CD34$^{\text{dim}}$CD45RA$^+\alpha_4\beta_7^{\text{bright}}$ cell can differentiate into a CD56$^{\text{bright}}$ NK cell in the presence of IL-15. Five novel, discrete stages of NK cell development were characterized in situ within the same parafollicular region of SLT, each with differential expression of CD34, CD117, and CD94.[33,40,41] As development proceeds along this continuum, the acquisition of phenotypic markers occurs in a progressive, orderly manner and cells acquire the ability to secrete cytokines (e.g., IFN-γ) and display natural cytotoxicity. This orderly development in SLT from a CD34$^+$ subset to CD56$^{\text{bright}}$ NK cells suggests that CD56$^{\text{dim}}$ NK cells represent a terminally differentiated NK stage that follows CD56$^{\text{bright}}$ NK development.[42–44] The abundance of CD56$^{\text{dim}}$ NK cells in blood versus SLT and their loss of both CD117 (c-kit) expression and proliferative capacity, along with their acquisition of KIR, FcγRIII (CD16), and cytolytic granules, are all consistent with this notion.[41] CD57 has been identified as a surface marker of terminally differentiated NK cells.[45]

NATURAL KILLER CELL RECEPTORS

In place of antigen-specific receptors, NK cells express a complex repertoire of surface molecules that allow them to efficiently recognize malignant and virally infected cells as non-self and rapidly initiate an appropriate immune response.[46,47] NK cell receptors may be activating or inhibitory. The binding of the NK cell receptor to its cognate ligand expressed on the surface of a target cell may either activate or suppress a functional NK cell response. Such receptors fall into three general categories: (1) those that are members of the KIR superfamily, (2) receptors that belong to the C-type lectin receptor (CTLR) superfamily, and (3) natural cytotoxicity receptors.[48] Currently, investigators are working from a model in which NK cell reactivity is determined in large part by the recognition of target cell major histocompatibility complex (MHC) class I alleles, with the presence of other target cell antigens providing additional signals to the NK cell (Fig. 21.2). MHC alleles are expressed on most human cells and may be classified as human leukocyte antigen A [HLA-A],[49] HLA-B,[50] and HLA-C[51] and their role in suppressing NK cytotoxicity is well-established.[52]

Killer-Cell Immunoglobulin-Like Receptors

KIRs provide one method by which NK cells recognize self from non-self in order to mediate an appropriate cytotoxic response. In total, 16 KIR genes have been identified on chromosome 19q13.4. Structurally, the KIR protein contains two or three extracellular immunoglobulin-like domains that have the ability to recognize MHC class I proteins, namely HLA-A, HLA-B, and HLA-C.[53] KIRs may be either inhibitory or activating, a functional feature that derives from the structure and enzymatic activity of the intracellular tyrosine-based motif of the KIR protein. An examination of KIR nomenclature provides information on the number of extracellular domains, the function of the intracellular motif, and the existence of polymorphic versions. The designation 2D or 3D indicates the number of immunoglobulin-like extracellular domains, while the length of the intracytoplasmic tail may be either long (L) and inhibitory, or short (S) and activating. A suffix numeral appearing at the very end of the KIR nomenclature indicates the existence of a polymorphic form of that particular receptor. For example, the terms KIR2DS2 and KIR2DS3 indicate the polymorphic forms of an activating KIR that displays two extracellular domains. The KIRs have been designated as members of the CD158 series.[53]

The KIR molecules provide NK cells with the ability to sense the absence of self-HLA molecules on potential target cells—a process which was originally referred to by K. Karre and early investigators as the detection of "missing self."[54–56] The 16 KIR genes are encoded by a family of homologous genes 10-16 kb in size that have been mapped to chromosome 19q13.4 where they are tightly arranged in a head-to-tail fashion. There are 14 KIR genes and 2 KIR pseudogenes. There are eight inhibitory KIR (KIR2DL1, 2DL2, 2DL3, 2DL5, 3DL1, 3DL2, and 3DL3) and six activating KIR (KIR2DS1, 2DS2, 2DS3, 2DS4, 2DS5, and 3DS1). The pseudogenes are designated KIR2DP1 and KIR3DP1). The long tails of the inhibitory KIRs contain 1 or 2 copies of immunoreceptor tyrosine-based inhibition motifs (ITIMs) that undergo phosphorylation following interaction with specific

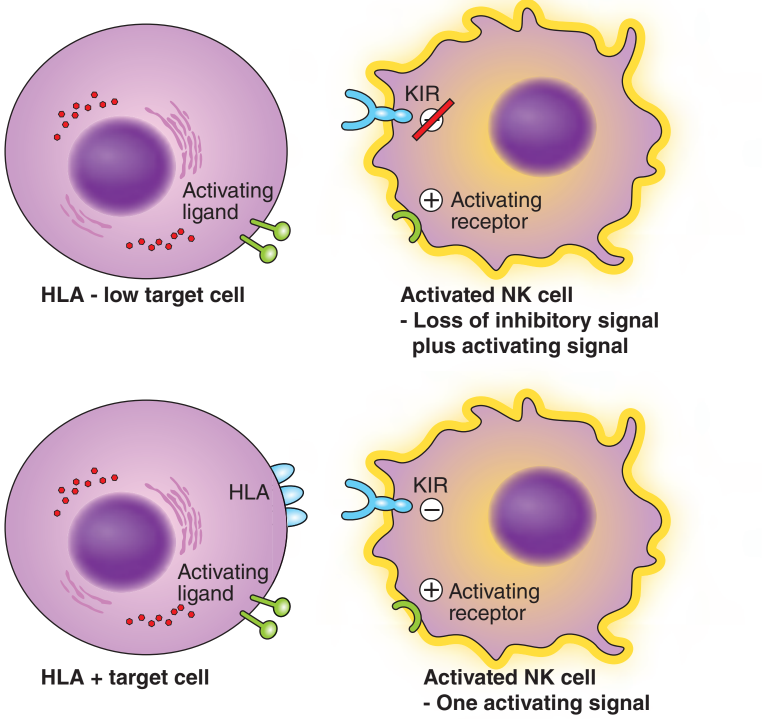

Figure 21.2 SIMPLIFIED REPRESENTATION OF NATURAL KILLER CELL CYTOTOXICITY MEDIATED THROUGH THE BALANCE OF ACTIVATING AND INHIBITORY SIGNALING IN RESPONSE TO LIGANDS ON POTENTIAL TARGETS. The NK cell in the top panel is stimulated to lyse the target cell due to the presence of activating ligands and absence of cognate HLA molecules, which leads to loss of inhibition through KIR. The NK cell in the bottom panel receives inhibitory signals by way of HLA-KIR interactions but is stimulated to lyse the target cell due to its expression of activating ligands. *HLA*, Human leukocyte antigen; *KIR*, killer immunoglobulin-like receptor; *NK*, natural killer.

HLA class I ligand and recruit Src homology region 2 domain containing phosphatase 1 and 2 (SHP-1, -2) that switch off the NK cell response. The short-tails of the activating KIRs lack ITIMs and instead are characterized by a positively charged amino acid residue in the transmembrane region that promotes the interaction with the 12 kDa DNAX activation protein (DAP-12). DAP12 contains immunoreceptor tyrosine-based activation motifs which initiate activating signals in response to ligand binding.[53]

Since they are organized in the form of a tightly linked cluster, the KIR genes are inherited as haplotypes with an individual receiving maternal and paternal contributions. KIR3DL3, 3DP1, 2DL4, and 3DL2 are present in every haplotype and are referred to as "framework" genes. KIR3DL3 is located at the 5′ centromeric end of the haplotype and KIR3DL2 is located at the 3′ telomeric end with KIR3DP1 and KIR2DL4 being located in the middle of the KIR gene complex separated by a 14 kb sequence that is enriched with L1 repeats. Thus, the centromeric half of the KIR haplotype is delimited by KIR3DL3 and 3DP1, and the telomeric half is delimited by KIR2DL4 and 3DL2. The KIR genes contained within these centromeric and telomeric regions enable the KIR haplotypes to be broadly classified into two categories, namely group A or group B. Group A haplotypes exhibit a fixed gene content that consists of KIR3DL3…2DL3…2DP1…2DL1…3DP1…2DL4…3DL1…2DS4…3DL2 in that order, with the framework genes having been underlined. In contrast, group B haplotypes are variable both in the number and combinations of KIR genes and contain several KIR genes (2DL2, 2DL5, 2DS1, 2DS2, 2DS3, 2DS5, 3DS1) that are not part of the A haplotype. Group A haplotypes contain only one activating gene (KIR2DS4), but group B haplotypes may contain up to five different activating KIRs, namely KIR2DS1, 2DS2, 2DS3, 2DS5, and 3DS1.

KIRs recognize specific peptide motifs of HLA class I molecules which are the products of MHC genes located on chromosome 6. The human MHC encodes for six functional HLA class I genes. HLA-A, HLA-B, and HLA-C represent the so-called classical class I genes and are highly polymorphic. The genes for HLA-E, HLA-F, and HLA-G encode non-classical class I molecules that are conserved. All of these class I molecules interact with NK cell receptors with the receptors for HLA-F having only recently been identified (Fig. 21.3). The alleles of the HLA-C locus can be placed into two groups of ligands (C1 and C2) based on the amino acid present at position 80 of the protein. HLA-C group 1 with asparagine at position 80 provides the ligand for KIR2DL2 and KIR2DL3, whereas HLA-C group 2 with lysine at position 80 provides the ligand for KIR2DL1. The HLA-Bw4 epitope at residues 77–83 of the HLA-B α1 domain is recognized by KIR3DL1. HLA-A3/11 serves as the ligand for KIR3DL2. While the ligands for inhibitory KIR have become well-defined, the ligand specificity of the activating KIR remains a subject of investigation. Recent studies indicate that KIR2DL4 is able to mediate both inhibitory and activating functions. Also, in addition to recognition of HLA-C1, KIR2DL2/L3 can weakly recognize some HLA-C2 alleles and the HLA-B*4601 and HLA-B*7301 alleles that bear the HLA-C1 epitope.[53,56]

Genotyping efforts reveal that all human populations possess group A and group B haplotypes, but their frequencies vary considerably. People of European descent and African Americans commonly carry both A and B haplotypes, whereas the homozygous group-A KIR haplotype (AA genotype) is common in Northeast Asians (i.e., Japanese, Koreans, and Chinese). The AB or BB genotypes are common in the Indigenous populations of India, Australia, and America and the NK cells of these individuals may contain up to 6 activating

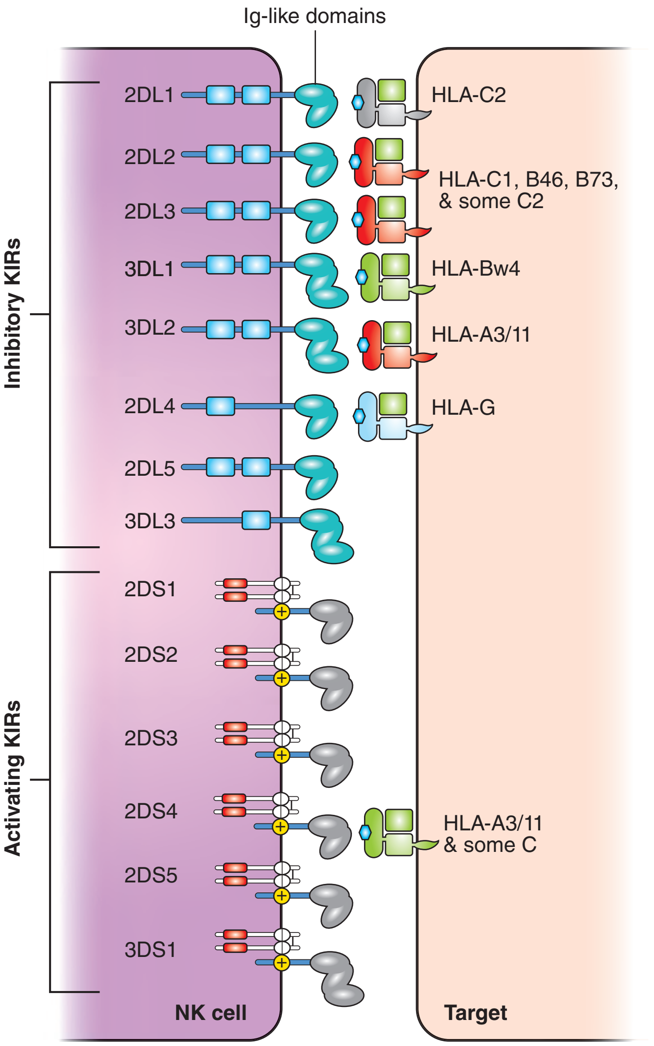

Figure 21.3 SIMPLIFIED REPRESENTATION OF HUMAN KIR MOLECULES AND THEIR HLA LIGANDS. There are 16 human KIR genes, 8 inhibitory, 6 activating, and 2 pseudogenes (not shown). The known HLA ligands are presented as binding partners. The ligands for several of the stimulatory KIRs have not yet been confirmed. *HLA*, Human leukocyte antigen; *Ig*, immunoglobulin; *KIR*, killer immunoglobulin-like receptor. *(From Rajalingam R. Diversity of killer cell immunoglobulin-like receptors and disease. Clin Lab Med. 2018;38(4):637–653.)*

KIRs. The prehistoric migrations of these populations may have provided environmental selective pressure in favor of haplotypes enriched in activating KIR.[57]

Individual KIR genes exhibit a high level of allelic polymorphism that can affect protein expression, affinity for HLA molecules, strength of the inhibitory/activating signal, and downstream cytotoxicity and cytokine release. The inhibitory KIR exhibit greater sequence polymorphism than the activating KIRs. Generally, inhibitory receptors bind with greater avidity or attraction for a corresponding HLA antigen than activating receptors.[58] Thus, if an NK cell expresses both activating and inhibitory KIR for an identical ligand, the NK cell will generally be inhibited from killing. Combinations of HLA variant and KIR genes exert an influence of resistance to viral infections, susceptibility to some autoimmune diseases, several pregnancy syndromes as well as the outcome of bone marrow transplantation.[59] Specific KIR/HLA allele pairings have been associated with improved outcomes in HIV[60,61] and hepatitis C infection.[62]

KIR2DL4 is present in all KIR haplotypes, and the presence of a positively charged arginine in its transmembrane region and a single ITIM moiety enables it to generate both a weak inhibitory signal as well as an activation program that leads to the secretion of proinflammatory and proangiogenic cytokines. HLA-G is expressed almost exclusively in fetal trophoblast cells at the maternal-fetal interface and its soluble form is the only known ligand for KIR2DL4 which is localized to NK cell endosomes. Uptake of soluble HLA-G by NK cell endosomal KIR2DL4 leads to endosomal signaling and the secretion of a collection of factors that favors embryo implantation, placental development, and successful pregnancy.[63,64]

C-Type Lectin Receptors

The CTLRs, located on human chromosome 12p12.3, share a common subunit (CD94) covalently bonded to one of four closely related gene products of the NKG2 family.[2,65] CTLRs promote a second type of NK cell receptor–mediated killing and include NKG2A (and splice variant B), NKG2C, NKG2E (and splice variant H), and NKG2F.[65] NKG2D, which does not bind CD94 and shares little sequence homology to other NKG2 proteins, is discussed below. The CTLRs expressed on NK cells and cytotoxic T lymphocytes are activating except for CD94/NKG2A which is inhibitory.[66] CD94/NKG2A specifically recognizes the non-classical HLA-E class I molecule.[67] HLA-E*0101 and HLA-E*0103 are the only two alleles present worldwide. Tumor cells may exhibit upregulation of HLA-E expression, presumably to avoid NK cell cytotoxicity. High-level expression of HLA-E is associated with poor prognosis in several cancers, and blockade of this ligand-receptor interaction can enhance NK cell anti-tumor activity.[68] HLA-E is able to present leader peptides from other HLA molecules which provides an additional mechanism for NK cells to sense the expression of class I MHC molecules on the cell surface. As is seen with KIR interactions, binding of CD94/NKG2A to HLA-E is more avid than binding of activating CTLRs to other epitopes.[69]

NKG2D is a CTLR; however, it does not associate with CD94 and has limited sequence homology with other members of the NKG2 family. NKG2D exists as a homodimer and does not have intrinsic signaling capacity, but instead interacts with the DAP10 adapter molecule which is able to provide signals that recruit the p85 subunit of phosphatidylinositol 3-kinase and a complex of GRB2 and VAV1.[70] This signal transduction arrangement effectively isolates the NKG2D signal from inhibitory signals that can suppress NK cell activation by other CTLRs. NKG2D is constitutively expressed at high levels on all NK cells, as well as on γδ T cells and $CD8^+$ T cells.[71] NKG2D binds to two different classes of MHC-I-like ligands whose expression is markedly induced by cellular stress, such as viral infection or malignant transformation. This binding event then leads to enhanced degranulation/cytotoxicity and production of IFN-γ. The ligands for NKG2D include the highly polymorphic MHC class I chain–related proteins MICA and MICB and 6 members of the UL16 binding proteins (ULBPs).[72–74] MICA and MICB expression is under the control of promoter elements similar to those that regulate the heat shock proteins which are upregulated in malignant cells and also those infected with cytomegalovirus (CMV).[75–78] UL16 is a virus-encoded type I transmembrane protein expressed in the setting of CMV infection that binds to ULBP-1 and ULBP-2 and allows the virus-infected cell to escape NK cell surveillance.[74,79] Similarly some human tumors downregulate expression of NKG2D ligands or release soluble forms of MICA as a mechanism of immune escape from NK cells.[80–83] Conversely, MICA expression by normal monocytes could provide a stimulus to NK cell activity against antibody-coated tumor cells.[84]

Natural Cytotoxicity Receptors

A third family of NK receptors that participate in the process of target cell recognition and elimination mediate cell killing are referred to as natural cytotoxicity receptors (NCRs). The three major NCRs that have been found to impact NK cell activation are NKp46, NKp30, and NKp44. NKp46 and NKp30 are uniquely and constitutively expressed on NK cells, and NKp44 is expressed on NK cells after cytokine stimulation (e.g., IL-2) and also on some γδ T cells.[85–87] Studies with neutralizing mAbs demonstrated that these receptors were recognizing ligands present on the surface of NK-susceptible targets, such as tumor cells and virally infected cells. The NCRs are type I transmembrane proteins that possess one or two immunoglobulin-like extracellular domains and a positively charged lysine or arginine in their hydrophobic transmembrane domain that allows them to interact with the ITAM-containing proteins and transduce an activating signal upon ligand binding. The CD56^{bright} and CD56^{dim} populations both express NKp46 and activation of this receptor promotes its association with CD3zeta or FcRgamma and drives the production of IFN-γ and TNF-α. NKp30 is expressed constitutively on all resting and activated NK cells. Its transmembrane region possesses a charged arginine residue that promotes a linkage with CD3zeta or FcRγ much like NKp46. Alternative transcript splicing gives rise to six different isoforms of NKp30, one of which (NKp30c) promotes NK cell secretion of the immunosuppressive cytokine IL-10 and is associated with reduced overall survival in patients with GIST tumors and neuroblastoma. NKp44 possesses a single extracellular V-type Ig domain that is connected to a lysine-containing transmembrane segment by a long stalk. The charged lysine residue enables the association of NKp44 with the DAP12 ITAM adapter which generates a stimulatory signal upon ligand binding. Notably, the intracellular region of the NKp44 protein contains an ITIM and thus has the ability to transmit both inhibitory and stimulatory signals. NK cell expression of NKp44 is markedly upregulated in the presence of IL-2, IL-15, or IL-1β.[88]

A large number of NCR activating ligands have been identified which permit NK cell recognition and elimination of malignant and pathogen-infected cells.[88] The costimulatory molecule B7-H6 is expressed at high levels on tumor cells and has been identified as an activating ligand for NKp30 that induces NKp30-dependent cytotoxicity. Some tumors shed a soluble form of B7-H6 that is associated with NK cell dysfunction and impaired tumor surveillance.[89,90] Heparin sulfate (HS) glycosaminoglycans are long chains of branched anionic polysaccharides that promote tumorigenesis by altering the extracellular milieu and providing a docking site for the basic portions of secreted growth factors. Each NCR recognizes a distinct HS sequence and mediates an activating signal upon binding.[91] NKp44 is also able to recognize nuclear proteins that undergo cell surface expression in the setting of malignant transformation or viral infection such as proliferating cell nuclear antigen (PCNA) that is normally expressed in the nucleus but can become complexed with HLA on the surface of lymphoma cells to form an inhibitory ligand for NKp44.[92]

NKp44 and NKp46 recognize hemagglutinin-neuraminidases (HN) expressed on the surface of cells infected with parainfluenza, Newcastle and Sendai virus, and also hemagglutinins (HA) from influenza infected cells. HA from the vaccinia poxvirus also bind to NKp30 and NKp46. Virus-mediated cleavage of sialic acid residues from NKp46 disrupts its binding to HA and inhibits NK cell elimination of infected cells.[93,94] NCR have the ability to recognize a broad array of pathogen-derived molecules. There is evidence that NKp44 and NKp46 play a role in the control of *Mycobacterium tuberculosis* and *Pseudomonas aeruginosa*. NKp30 and NKp46 are able to recognize proteins on the surface of erythrocytes infected with *Plasmodium falciparum* (cause of malaria) as well as fungal antigens from *Candida glabrata*, *C. neoformans*, and *C. albicans*. These beneficial effects of NCR-driven NK cell activity are balanced by studies that implicate these receptors in allergic disease and autoimmune conditions.[88]

Other Activating Receptors

DNAX accessory molecule-1 (DNAM-1) is a member of the immunoglobulin-like superfamily that is constitutively expressed on the surface of NK cells as well as T cells and macrophages. The ligands for DNAM-1 are the poliovirus receptor (PVR, or CD155) and Nectin-2 (herpes entry mediator B—HVEB or CD112). PVR and Nectin-2 become upregulated in response to cellular stress such as occurs with viral infection or malignant transformation. Engagement of DNAM-1 on the NK cell by PVR or Nectin-2 on the target cell initiates a signaling cascade that results in activation of ERK and AKT followed by calcium mobilization and the onset of NK cell effector functions. DNAM-1-mediated NK cell activation is counterbalanced by CD96 (also known as TACTILE) and TIGIT, two inhibitory NK cell receptors that belong to the same immunoglobulin-like superfamily as DNAM-1. CD96 is able to bind to PVR while TIGIT recognizes both Nectin-2 and PVR. These nectins may thus deliver either activating or inhibitory signals to the NK cell.[95] Also, the ability of a soluble, tumor-derived PVR molecule to inhibit NK cell degranulation and promote the pulmonary spread of tumor in a murine model of melanoma suggests a role for DNAM-1 in NK cell anti-cancer activity.[96]

CD244 (2B4) is an NK cell immune regulatory transmembrane receptor belonging to the signaling lymphocyte activation (SLAM) family. Its two extracellular Ig-like domains permit binding of CD48 (receptor on hematopoietic cells) and its cytoplasmic domain contains four immunoreceptor tyrosine—based switch motifs (ITSMs) that generate inhibitory or activating signals based upon the binding of distinct adaptor molecules with positive (SAP-Signaling lymphocyte activation molecule-associated protein) or negative (SHP-1, SHP-2, SHIP) effects. The expression levels, availability, and relative binding affinity of these adaptor molecules determine the output of CD244 in terms of its ultimate inhibitory or activating effects.[97,98] CMV viruses produce a soluble CD48 decoy protein that masks the 2B4 protein and inhibits the NK cell anti-virus responses.[99]

ADAPTIVE IMMUNE PROPERTIES OF NATURAL KILLER CELLS

NK cells have traditionally been thought of reacting to target cells in a largely stochastic fashion based on the presence or absence of specific receptors and their corresponding ligands. However, emerging data suggest that NK cells demonstrate sophisticated adaptive capabilities that improve the response to pathogens while limiting autoreactivity. Cues in the tissue microenvironment originating from interactions with normal cells and target cells can have a long-lasting impact on the NK cell compartment.[100]

Natural Killer Cell Education

The location of the KIR gene locus on chromosome 19 and the existence of the HLA locus on chromosome 6 has significant impact on the optimal functioning of the NK cell compartment. The potential for NK cell autoreactivity exists because NK cells in any one individual may lack inhibitory receptors for a particular self molecule, or the NK cell population may actually express activating receptors for self ligands. This situation can occur because the receptor array expressed on NK cells is determined in a random fashion through inheritance, and the ligands corresponding to these receptors are inherited independently. We now know that there exists a system of "education" whereby potentially autoreactive NK cells are not clonally deleted but rather rendered hyporesponsive in order to generate a state of self-tolerance. Conversely, NK cells that have engaged self-MHC via the appropriate inhibitory receptors may be thought of as being "licensed" to respond to subsequent stimulatory signals provided by target cells that lack self-MHC molecules.[101] Two different models of NK cell licensing have been proposed to explain the differential responsiveness of NK cell populations. The "arming" model proposes that NK cells lacking inhibitory receptors self-MHC simply fail to achieve full reactivity, whereas a "disarming" model predicts that NK cells that lack the inhibitory receptors for self MHC class I molecules are rendered hyporesponsive due to chronic low-level stimulation by activating receptors.[102] Evidence for the arming models comes from experimental murine models in which the functional maturation of NK cell precursors is enhanced following interactions with normal cells that express cognate MHC class I molecules during the course of development.[103–105] Support for the disarming model derives from experiments in which NK cell hyporesponsiveness is achieved when normal cells provide excessive stimulatory signals in the absence of inhibitory signals.[106–108] Although there is evidence to support each model, it is also possible that these two systems of education are both active and working together simultaneously. In fact, a so-called rheostat model has been proposed that describes a continuous process in which the availability of receptor ligands within the normal environment leads to differential and ever-changing engagement of the NK cell receptor repertoire such that the cellular response becomes "tuned" to an optimal set point.[102]

Natural Killer Cell Memory

In contrast to T and B cells, NK cells do not express the recombinase genes necessary for generating receptor variability and have a limited repertoire of germline encoded receptors for the identification of target cells that should be eliminated. Immunologic memory is a hallmark of the adaptive immune system wherein lymphocytes recognize a previously encountered antigen and rapidly respond with a highly specific immune response. However, recent data suggest that NK cells possess a form of memory as well. This idea was first demonstrated in a recombinase-activating gene 1 (RAG-1)-deficient mouse lacking T and B cells that were treated with haptens—that is small molecules that interact with host proteins to form immunogenic adducts. Despite the absence of adaptive immunity, mice rechallenged with the hapten developed a measurable hypersensitivity type recall response that was dependent on the existence of "memory" NK cells residing in the liver and expressing Thy1 and CXCR6.[100] The concept that murine NK cells can exhibit an adaptive immune response to haptens has also been demonstrated in the setting of viral infection with vesicular stomatitis virus, HIV-1, influenza, vaccinia, varicella-zoster virus, and hepatitis B.[109–113]

A second example of adaptive NK cell responses has been identified in the setting of human and murine CMV (MCMV) infection. Ly49H$^+$ NK cells recognize the MCMV m157 glycoprotein, resulting in NK cell–mediated control of the disease. These Ly49H$^+$ NK cells preferentially expand in the setting of infection and contract under the direction of the proapoptotic factor Bim once the infection is controlled.[114,115] However, "memory" NK cells can be detected months after infection, and, upon restimulation, these NK cells exhibited augmented cytotoxicity and cytokine production against MCMV.[81] These NK cells stably express KLRG1, a cadherin-recognizing inhibitory receptor, and could be detected two months after infection control. CMV infection in humans is associated with expansion of NK cells expressing NKG2C, the human homologue of murine Ly49H that respond to CMV reactivation with enhanced anti-viral effector functions.[116,117]

A third type of functional NK cell memory has been reported by Cooper et al. in murine NK cells that were briefly pre-activated with IL-12, IL-15, and IL-18 and exhibited enhanced IFN-γ output in response to restimulation for up to 3 weeks.[118] This training effect could be passed on to subsequent generations of NK cells and was associated with increased expression of CD94, NKG2A, NKp30, NKp44, NKp46, CD62L, and CD25 expression and no change in levels of CD57 and KIR molecules.[119] Many of the features associated these cytokine-induced memory-like (CIML) NK cells are also seen in human NK cells and their response to tumor targets. This observation has provided a rationale for infusion of CIML NK cells in the clinical setting.[120]

THE ROLE OF NATURAL KILLER CELLS IN HUMAN DISEASE

Studies of individuals with impaired or dysfunctional NK cell activity have shed new light on the genes and mechanisms responsible for proper NK development and function. Several syndromes have been linked to increased susceptibility to infection, while others may predispose to autoimmune disease and possibly the development of malignancy.

Natural Killer Deficiency Syndromes Linked to Increased Infectious Risks

Pure NK cell deficiency syndromes may be the result of a profound decrease in the number of circulating NK cells, or may reflect a serious defect in NK cell function but with normal numbers of NK cells in the peripheral blood.[121] Patients with classical NK cell deficiency present with a history of severe, recurrent infections caused by members of the Herpesviridae and Papillomaviridae families that usually have a benign course in normal individuals. CD56+ NK cells are either absent or represent less than 1% of circulating lymphocytes. Biron and colleagues reported in 1989 on the case of a young patient who presented with life-threatening varicella infection who exhibited an absolute absence of CD56$^+$CD16$^+$ NK cells. This individual subsequently developed CMV pneumonia and cutaneous HSV (herpes simplex virus) infection.[6] A second patient with a similar lack of peripheral blood NK cells presented with disseminated *Mycobacterium avium* infection and went on to die as a result of systemic varicella infection.[122] Other patients have been described with an isolated deficiency of CD56$^+$/CD3$^-$ lymphocytes but with normal or even increased populations of CD56$^+$/CD3$^+$ cells. One such patient presented with severe, recurrent condylomatous disease caused by the human papilloma virus.[123] An example of a gene mutation causing a functional NK deficiency in NK cell cytotoxicity is the substitution of "T → A" at gene position 230 in *FCGR3*A (codes for FcγRIIIa) resulting in the replacement of a histidine residue with lysine. Affected patients experience increased susceptibility to severe and disseminated HSV infections as well as Epstein-Barr virus and varicella infections.[124,125]

The Role of Natural Killer Cells in Autoimmunity

NK cells have been implicated in both the regulation and pathogenesis of autoimmune disorders. NK cells have been implicated in preventing the progression of paralysis in murine experimental models of MS.[126] Recently, investigators have identified CD56$^{\text{bright}}$ NK cells as a possible biomarker of response in MS following treatment with interferon-beta.[127] NK cells have also been shown to control inflammation in an experimental model of autoimmune colitis.[128,129] Experimental evidence supports the idea that NK cells may promote development of type 1 diabetes mellitus through targeted elimination of pancreatic islet β cells after viral infection.[130] This pathobiology may be mediated via an as yet unidentified NKp46 ligand located in the insulin granules of beta cells.[131,132] Other studies suggest that NK cells can promote humorally mediated autoimmune diseases such as myasthenia gravis through potentiation of autoreactive B cells.[133] Synoviocytes of patients with rheumatoid arthritis (RA) have been shown to express abnormally high levels of MICA, a ligand for NKG2D.[134] NK cells present in acute RA joint effusions may perpetuate this autoimmune inflammatory response,[135] and an analysis of synovial fluid NK cells in patients with severe RA revealed a marked expansion of a CD56$^{\text{bright}}$ population with high-level expression of CD69 and NKp46.[136] There is also evidence for NK cell participation in the process of RA bone destruction.[137]

Polymorphisms of the FcγRIIIA gene have been implicated in the pathogenesis and progression of autoimmune disease such as systemic lupus erythematosus (SLE) and RA.[138–141] There is evidence for an association between NK cell KIR expression and the onset of several autoimmune diseases. The frequency of KIR2DS2 has been identified as being significantly elevated in individuals with SLE.[142] The KIR2DS gene has also been associated with the onset of psoriatic arthritis.[143] Behçet disease is a rare autoimmune disease affecting blood vessels. A comprehensive analysis of HLA and KIR genotypes in over 300 patients suggested that the NK cell KIR repertoire is very likely involved in Behçet disease pathogenesis.[144] Particular KIR genes have also been linked to the development of RA, MS, type 1 diabetes, and ankylosing spondylitis, among others.[145]

THE THERAPEUTIC POTENTIAL OF NATURAL KILLER CELLS

In order to generate an antitumor immune response and eliminate malignant cells, T lymphocytes require the presence of a tumor-specific antigen. These targets have been difficult to identify for the majority of non-viral neoplasms. In contrast, it has long been recognized that NK cells are capable of mediating an antitumor effect in the absence of identifiable tumor antigens. As our understanding of NK cell biology has progressed, investigators have developed a number of innovative approaches to cancer therapy based on the use of NK cells (Table 21.2).

Natural Killer Cells and Hematopoietic Cell Transplantation

In greater than 95% of cases of patients undergoing hematopoietic cell transplantation (HCT) for leukemia, haploidentical individuals are available to act as donors of bone marrow or peripheral blood stem cells. Mismatches between donor KIR and recipient HLA create the potential for donor NK cell reactivity against leukemic cells as well as normal tissues within the recipient. Donor NK cells do not mediate significant graft-versus-host disease (GVHD) in the setting of HCT, likely due to the absence of significant activating signals being delivered by normal cells. In contrast, an effective NK cell-mediated graft-versus-leukemia (GVL) effect is possible when KIR on donor NK cells fail to encounter cognate HLA ligands on residual leukemic cells within the recipient. In 2002, Ruggeri et al. were the first to establish that the risk of relapse in acute myeloid leukemia (AML) following haploidentical HCT was markedly lowered when NK cell-based alloreactivity was present based on KIR-HLA mismatch in the GVL direction and the existence of alloreactive NK cell clones with the ability to lyse recipient leukemic cells.[146] These results were confirmed in a larger study of 112 AML patients where transplantation in the setting of complete remission with a NK cell alloreactive donor was associated with a significantly reduced relapse rate of 3% compared to 47%. Similar results were obtained for patients transplanted in relapse (6% vs. 34%).[147] Variable results have been obtained in subsequent studies that reported the outcomes of KIR mismatched HCT that utilized various donor sources, such as umbilical cord

TABLE 21.2 Anti-Cancer Therapies That Employ or Activate Natural Killer Cells

Therapy	Example	Advantages	Disadvantages
Exogenous cytokines	IL-2 IL-12 Interferon-alpha	Availability/low cost Can be combined with other agents	Toxic at high doses Off-target effects
Monoclonal antibodies ±NK cell stimulatory agents	Trastuzumab (anti-HER2 mAb)	Relatively inexpensive Known toxicity profiles Repeat dosing possible	Limited number of targets mAb therapy usually given w/ chemotherapy which can deplete NK cells
KIR blockade	Lirilumab (blocks KIR2DL1/2/3)	Blocks key NK inhibitory pathway	Ineffective as single agent
Checkpoint blockade	anti-TIM-3 mAb anti-TIGIT mAb	Ease of mAb administration	Checkpoints not universally expressed on all NK cell subsets
Engage activating receptor	Agonistic Abs to NKG2D, NKp46, CD137	Multiple targets on NK cells	Inhibitory pathways still active
Multivalent molecules	Bispecific killer engager (BiKE) to engage CD16 and tumor antigens	Molecule directs and activates NK cells	Tumor antigen target is required
Expansion of NK cells in vivo via cytokine administration	Low-dose IL-2 infusions IL-15 infusion	Well-tolerated Effectively expands NK cell populations	IL-2 can induce Treg cells Low anti-tumor activity as a single agent
Autologous NK cell Infusions	Lymphokine-activated killer (LAK) cells±IL-2	Relatively low side-effects	Need for expansion of the graft ex vivo Limited persistence of graft in recipient
Allogeneic NK cell Infusions	IL-2-activated NK cells from related haplo-identical donors	Availability of graft	Requirement for lymphodepleting chemotherapy Short-term persistence of graft
Hematopoietic cell transplantation (HCT) for leukemia	HCT for AML with haploidentical donor	GVL effect Less chance for GVHD	Requirement for lymphodepleting chemotherapy
CAR-NK cells	Multiple approaches	Highly modifiable Multiple cell sources	Need for genetic modification of NK cells Need for sophisticated manufacturing processes Limited lifespan Given after lymphodepleting chemotherapy

For abbreviations, see text.

blood, and sibling or unrelated donors.[148] The precise mechanisms involved in the generation of an NK vs. leukemia effect are complex given the independent inheritance of KIR and HLA genes, and the large variety of KIR interactions that can occur post-transplant. Also, the strength of this effect can be influenced by the type of preparative chemotherapeutic regimen, graft dose, T-cell depletion strategy, and post-transplant conditioning regimens.[149] Since a KIR mismatch requires the absence of a host KIR ligand that is present in the donor, NK alloreactivity is taking place in the setting of a major HLA-class I mismatch, and thus the extent of graft T-cell depletion becomes important. Indeed, the presence of T cells in the graft can adversely impact NK cell reconstitution.[150] Given the diversity of KIR expression and the existence of multiple alleles with variable binding capacity and levels of expression, it is recommended that KIR genotyping for HCT be accompanied by phenotyping via cytometric methods or quantitative PCR with an evaluation of the ability of donor NK cells to kill allogeneic recipient targets, such as PHA lymphoblasts and/or leukemia cells.[151] In adults, the beneficial effects of NK cell GVL activity are most prominent for AML rather than ALL; however the event-free survival post-HCT of pediatric ALL patients was significantly better for KIR B haplotype donors than for A haplotypes.[152] The association of the KIR B haplotype with improved survival is also seen in the setting of unrelated donor HCT for AML and non-Hodgkin lymphoma.[153,154] Activating KIR can also play a role in HCT outcomes, as evidenced by a significant reduction in infectious complications and non-relapse mortality when there was a GVL effect driven by the activating KIR2DS1 and KIR3DS1.[155] Finally, in a study of over 600 patients receiving reduced intensity HCT, CMV reactivation was associated with improved disease-free survival and the expansion of a CMV-responsive population of NK cells with reduced expression of CD56 and elevated surface levels of CD57 and NKG2C.[156]

Infusion of Autologous Natural Killer Cells

In studies conducted in the 1980s, peripheral blood mononuclear cells (PBMC) from patients with metastatic melanoma were expanded in vitro with IL-2 and the resulting lymphokine-activated killer cell (LAK) preparations (which likely had CD56+ NK cells as their precursors) were re-infused, usually with the addition of intravenous high-dose IL-2.[157] Complete responses were seen in about 10% of patients, but IL-2 administration was associated with a vascular leak syndrome and liver damage in some individuals. Given the evidence for NK cell anti-tumor activity in the setting of HCT, direct infusion of pure NK cell preparations has been performed as primary therapy in patients with leukemia and solid tumors.[158,159] However, the infusion of unmodified autologous NK cells has not shown significant anti-tumor activity. No clinical responses were observed when autologous NK cells were isolated from T-cell-depleted peripheral blood, cultured with IL-2, OKT3 (stimulatory anti-CD3 mAb) and irradiated autologous peripheral blood cells for 10 days and then infused into lymphodepleted patients with metastatic melanoma or renal cell carcinoma.[160] Similarly, patients with advanced breast cancer or lymphoma did not respond to the infusion of an autologous lymphapheresis product that had been cultured overnight with IL-2.[161]

Infusion of Allogeneic Natural Killer Cells

Outside the setting of HCT, the persistence of infused allogeneic NK cells is restricted by the recipient's immune system which is able to reject the graft. However, rejection of the donor NK cells can be delayed by pre-treating the recipient with lymphodepleting chemotherapy. Miller et al. employed this principle in a study that administered IL-2-activated NK cells (1×10^5–2×10^7 cells/kg) from related haploidentical donors to patients with metastatic solid tumors and also to individuals with poor-prognosis AML. Low-dose IL-2 (10 MU thrice weekly) was administered post-infusion. A lower intensity chemotherapy regimen was associated with NK cell persistence but did not lead to NK cell expansion. In contrast, AML patients receiving a more intensive inpatient regimen of high-dose cyclophosphamide and fludarabine exhibited expansion of the NK cell graft, endogenous production of IL-15, and complete remission of their leukemia in 5 of 19 cases.[162] A follow-up phase II study of a similar regimen in patients with recurrent breast or ovarian cancer did not result in significant expansion of the infused NK cells.[163]

The procedures being used for allogeneic NK cell infusions have undergone substantial advances in terms of the source of NK cells and methods used for cell expansion.[164] Peripheral blood NK cells have been used in the majority of clinical studies to date. PBMC obtained by density gradient centrifugation of a leukapheresis product from a normal donor can be further purified via T-cell depletion. Increased NK cell purity can be achieved via magnetic bead selection for CD56+ cells.[165] Peripheral blood NK cells from healthy persons are in a resting state. Therefore, IL-2 has been used to activate and expand the NK cell graft with a four-fold expansion being observed after one week of culture.[166] The use of IL-15 in a clinically applicable culture protocol led to increased expression of genes supporting cell metabolism and respiration.[167] Combinations of cytokines have also been used (e.g., IL-12, IL-15, and IL-18) in an effort to generate an NK cell product with greater cytotoxic activity and longevity.[118,168] Inclusion of irradiated feeder cells such as the K562 cell line will stimulate NK cell expansion and genetically engineered K562 cell lines have been used to present combinations of stimulatory signals such as membrane bound IL-15 (mbIL-15) and 4-1BBL, the ligand for the OX40 activating receptor.[169] Umbilical cord blood can serve as a source of CD34+ hematopoietic stem cells that can be expanded and then differentiated into NK cells via culture in a cocktail of cytokines that includes stem cell factor, IL-7, and IL-15.[170] Induced pluripotent stem cells (iPSCs) are derived from somatic cells such as fibroblasts that have been transduced with reprogramming genes (classically, Oct4, Sox2, cMyc, and Kl4) and may therefore serve as a starting source of cells. iPSC are first cultured in conditions that induce a hematopoietic differentiation program followed by cytokine conditions that promote the differentiation of NK cells which are then propagated with a stimulatory cell line expressing a membrane bound cytokine (e.g., IL-15 or IL-21).[171,172] Prior to the infusion of allogeneic NK cells, chemotherapeutic agents such as cyclophosphamide and fludarabine are used to induce a lymphodepleted state which transiently depletes the immune cell compartment and permits the temporary engraftment of the infused NK cells.[173] IL-2 or IL-15 may be administered to the patient post-transplantation in order to support NK cell engraftment.[174] A study of s.c. rhIL-15 administered after lymphodepleting chemotherapy and infusion of haploidentical NK cells led to NK-cell expansion by day 14 in 27% of patients with remission being achieved in 40% of cases, but this regimen was associated with previously unreported cytokine release syndrome.[175] While most clinical studies have focused on the treatment of patients with hematologic malignancies (AML most commonly), studies have been conducted with some success in patients with neuroblastoma, melanoma, renal cell carcinoma, ovarian cancer, and breast cancer.[163] Manufacture of the NK cell product is resource intensive, and therefore some investigators have made use of the NK-92 cell line in place of primary NK cells. This $CD56^+CD3$ cell line has cytotoxic capabilities similar to NK cells, but the cells must be irradiated prior to infusion in order to prevent tumor transfer to the recipient, and this prevents further cell proliferation.[176] Strategies to enhance the efficacy of infused haploidentical NK cells involve the use of novel cell sources, improved expansion techniques, elimination of immune suppressor cells (e.g., regulatory T cells and myeloid-derived suppressor cells), and the blockade of inhibitory checkpoint molecules.

Expansion of Natural Killer Cells In Vivo via Cytokine Administration

NK cells have been successfully expanded in vivo in patients with cancer through the exogenous administration of recombinant human cytokines. IL-2 was the first cytokine to be employed as a means of driving NK cell proliferation in humans. Caligiuri and colleagues discovered that the CD56^{bright} subset of NK cells expressed a high-affinity IL-2R that was comprised of the IL-2R beta and gamma chains in combination with the alpha chain (IL-2Rα). This heterotrimeric receptor is capable of binding picomolar doses of IL-2 and mediates a very strong proliferative signal. Prolonged infusion of rIL-2 at doses of 1.5×10^5 and 4.5×10^5 U/m^2/day was well-tolerated in cancer patients and resulted in a 6- to 19-fold expansion of NK cells. Similar effects were seen in post-remission AML patients and individuals with HIV-associated malignancies.[177,178] Subsequent analyses indicated that IL-2 administration could induce the unwanted expansion of regulatory T cells.[179] The first in-human trial of intravenous rhIL-15 was associated with a greater than 10-fold expansion of NK cells with virtually no change in the regulatory T-cell population.[180] A novel superagonist form of IL-15 (ALT-803) is now in clinical development that consists of an IL-15/IL-15Rα complex linked to IgG1 Fc, in which IL-15 is additionally mutated (asn72asp) to further increase biological activity.[181] Phase I studies have demonstrated that this agent is well tolerated and induced the expansion of NK cells. Combination studies with other immune-activating agents (e.g., anti-PD-1 mAb) are now being conducted.[182,183] NK cell expression of receptors for stimulatory cytokines such as IL-12, IL-18, and IL-21 provide a rationale for clinical studies that administer these factors to patients with advanced malignancies, yet consistent single-agent anti-tumor activity has not been achieved. IL-12 (originally known as NK cell stimulatory factor) significantly enhances NK cell anti-tumor activity in pre-clinical models but was associated with IFN-γ-induced toxicity that has limited its clinical utility. Several innovative alternate routes of IL-12 administration are under investigation.[184]

Killer-Cell Immunoglobulin-Like Receptors Blockade

The interaction between inhibitory NK receptors and MHC class I receptors can be interrupted by means of monoclonal antibodies. Murine models lend support to the notion that tumor MHC class I molecules can engage inhibitory NK cell receptors to induce NK tolerance.[23] When antibody fragments were introduced to disrupt this ligand–receptor interaction, increased NK cytotoxicity and decreased tumor growth were observed. Thus blockade of inhibitory NK cell receptors represents a novel form of cancer immunotherapy.[185,186] Phase I clinical trials of an anti-KIR antibody that blocks KIR2DL1/2/3 (lirilumab) have shown that greater than 90% KIR occupancy could be achieved.[187,188] The combination of lirilumab with lenalidomide in patients with multiple myeloma was well-tolerated as was the combination of lirilumab with the anti-PD-1 mAb nivolumab; however, the observed clinical activity did not support further investigation in these settings.[189,190] It has been hypothesized that KIR blockade might prevent full maturation of the NK cell anti-tumor response and thus additional combinatorial strategies are being explored.

Natural Killer Cell Checkpoint Blockade

NK cells either constitutively or transiently express several other inhibitory molecules that represent negative regulators of immune activity or so-called immune checkpoints. These checkpoint molecules include PD-1, CTLA-4, TIM-3, LAG-3, IL-1R8, and TIGIT.[191] There is evidence that inhibition of these pathways with neutralizing antibodies could augment NK cell anti-tumor activity. A subset of CD56^{dim} NK cells expresses PD-1 and this correlates with reduced anti-tumor function and poor outcome in some cancer patients.[192–194] TIM-3 is a type I transmembrane protein belonging to the Ig superfamily that recognizes multiple ligands including phosphatidylserine and galectin-9. High-level TIM 3 expression correlates with NK cell exhaustion, which can be reversed by TIM-3 blockade.[195,196] LAG-3 is an NK-expressed inhibitory receptor that belongs to the Ig superfamily and recognizes several tumor-expressed proteins.[197] IL-1R8 is a member of the interleukin-1 receptor (IL1R) family and acts as a negative regulator of activation signals mediated by IL-1Rs and toll-like receptors (TLRs). IL-1R8 is able to down-regulate NK cell maturation and anti-tumor/anti-viral function.[198] TIGIT competes with DNAM for binding to ligands of the nectin family and when ligated mediates an inhibitory signal that leads to reduced NK cell cytotoxicity and IFN-γ production. Blockade of TIGIT in combination with IL-15 in a murine model of melanoma led to NK cell-mediated destruction of MHC class I-deficient tumors that were refractory to CD8+ T cell-mediated immunity.[199] These studies highlight the ability of inhibitory pathways to modulate NK cell activity.

Natural Killer Cell Antibody-Dependent Cytotoxicity

The ability of NK cells to recognize antibody-coated target cells and conduct ADCC and produce immune activating cytokines represents an anti-tumor mechanism that can be manipulated for therapeutic benefit. While antigen-specific mAbs are able to exert a direct antitumor effect, there is evidence that FcR-bearing immune effector cells (e.g., FcγRIIIa+ CD56^{dim} NK cells) may also be involved in the elimination of tumor cells.[200] Clynes et al. reported that the anti-tumor effects of trastuzumab in a murine model of breast cancer required the expression of functional FcγR by host immune effector cells.[201] And patients with single nucleotide polymorphisms that confer enhanced FcR binding to IgG may have improved outcomes to some mAb therapies.[202,203] Although granulocytes and monocytes co-express both activating and inhibitory FcγR, NK cells primarily express only the activating FcγRIIIa receptor.

Multiple strategies have been employed to enhance the NK cell response to antibody-coated tumor targets. The N-terminal glycosylation pattern of human IgG at Asn297 in the Cγ2 domain markedly impacts antibody affinity for the Fc receptor. Removal of the fucose group from the pentasaccharide core creates a non-fucosylated antibody with greater affinity for FcγRIIIa and an enhanced ability to mediate ADCC. Obinutuzumab is a non-fucosylated antibody with superior ADCC induction capabilities that recognizes CD20 and has clinical efficacy.[204] Cytokine stimulation of NK cells has been found to enhance NK cell ADCC and cytokine production.[205] Notably, in a murine model of HER2-expresssing cancer, co-administration of IL-12 with an anti-HER2 mAb generated synergistic anti-tumor activity that was dependent on NK cell production of IFN-γ.[206] In a phase I study of IL-12 in combination with the anti-HER2 mAb trastuzumab, sustained NK cell production of IFN-γ was observed only in patients who experienced clinical benefit.[207] In a follow-up study of IL-12 in combination with trastuzumab and paclitaxel, 50% of patients experienced tumor shrinkage or prolonged disease stabilization along with high levels of IFN-γ. NK cells were shown to be the source of cytokine production, and co-localization of the FcR and IL-12R was found to be responsible for synergistic NK cell activation.[208,209] IL-2 has also been used in combination with both trastuzumab and rituximab in order to expand NK cell numbers; however, Treg induction inhibited NK cell functioning.[210,211] Pre-clinical models support the use of other NK cell activating agents in combination with mAbs such as IL-15, IL-21, and TLR agonists.[212–214] Dual stimulation of NK cells via the FcγRIIIa and a cytokine receptor (e.g., IL-12R) results in the synergistic release of IFN-γ, TNF-γ, and GM-CSF, and T-cell chemokines including IL-8, MIP-1γ, MIP-1β, MDC, MCP-1, and RANTES[208]

Protein engineering techniques have permitted the development of novel reagents with multiple binding moieties that promote the engagement of NK cells with tumor targets and the generation of an immune synapse that stimulates an NK cell cytotoxic response. One group has created a novel bivalent protein that recognizes NKG2D on NK cells and CD138, a protein overexpressed by malignancies. This construct strongly activated NK cells and inhibited tumor growth in mice.[215] NK cell cytotoxicity can be triggered using bispecific molecules that simultaneously bind to CD16 on NK cells and a tumor antigen. Bispecific killer engagers (so-called BiKEs) are comprised of two single-chain variable fragments (scFv) which are fusion proteins of the variable regions of the heavy and light chains of an antibody (VH and VL) connected with a short linker peptide. In a BiKE, one scFv is specific for CD16 and the other for the tumor antigen of interest, such as CD19.[216] Tri-specific molecules that incorporate an activating cytokine are also being tested.[217]

Genetic Engineering of Natural Killer Cells

NK cells can be genetically modified to express new proteins that augment their ability to eliminate target cells and then infused for therapeutic purposes. The use of HLA-mismatched NK cells provides for an expanded menu of cell types that can serve as starting material. Strategies that have been employed include the expression of (1) modified activating receptors, (2) machinery to downregulate inhibitory receptors, (3) soluble or membrane-bound cytokine, and (4) chimeric activating receptors (CARs). Genetically modified NK cells may then be infused into cancer patients following lymphodepleting chemotherapy.

Based on the clinical success of CAR-T-cell therapy for CD19-expressing lymphomas[218] there has been considerable interest in generating analogous NK cell products or so-called CAR-NK. This approach has several theoretical advantages over CAR-T-cell therapies. While CAR-T-cell therapy requires genetic manipulation of autologous or HLA-matched T cells, CAR-NK may be generated from multiple different cell sources, and as is the case with HCT, HLA mismatches can be beneficial to the NK cell therapeutic effect. Reduced expression of MHC class I molecules or target antigen severely limits the cytotoxic capacity of infused CAR-T cells and represents an important mechanism of resistance to this form of cell therapy. In contrast, NK cells possess an innate ability to detect and eliminate such target cells due to the ability of NK cells to detect activating/stress ligands and missing self. Although NK cells have the ability to conduct serial killing, infused NK cells have a limited lifespan and have not been known to cause significant side effects or GVHD. On the other hand, CAR-T-cell therapy can result in serious and sometimes fatal toxicities including cytokine release syndrome and neurotoxicity in the form of immune effector cell-associated neurologic syndrome (ICANS). It is not always possible to obtain sufficient numbers of high-quality T cells from chemotherapy-refractory patients. Also, the manufacturing process can take 2 to 4 weeks and patients must have therapy held for at least 2 weeks prior to apheresis. Thus, the timely administration of CAR-T cells can be problematic in patients who have proven refractory to standard therapies. CAR-T-cell therapy requires post-treatment hospitalization for several weeks. In contrast, it is possible to envision "off-the-shelf" CAR-NK cell products being administered in the outpatient setting as a bridging therapy to patients experiencing recurrent disease.[218,219]

Advances made in the field of CAR-T-cell therapy have been applied to the development of CAR-NK cells.[220] The CAR structure usually consists of an extracellular scFv derived from an antibody against a tumor antigen, a hinge region connecting this antigen-recognition sequence to a transmembrane domain (TM), and one or more intracellular signaling domains. The scFv consists of a heavy and a light variable fragment (VH, VL) joined by a flexible linker. The binding affinities and order of the variable fragments as well as the length of the linker can impact CAR affinity for an antigen. The hinge sequence is typically based on known proteins with similar structure (CD8alpha, CD28, CH2/3 domains), and its length can be adjusted to optimize antigen binding. The TM domain is a hydrophobic region that crosses the cell membrane and serves to anchor the CAR. The choice of TM is important since some sequences can promote activation-induced cell death or alter CAR cell surface distribution. First-generation CAR-T constructs contained only a CD3zeta activating domain. However, subsequent generations included one or more additional co-stimulatory domains derived from either the TNF receptor family (4-1BB, CD27, OX40) or the CD28 family. CAR-NK constructs may contain NK-specific activating domains (e.g., DAP10 or DAP12) in place of or alongside CD3zeta. Co-stimulatory domains derived from 2B4 and CD137 have also been evaluated.[220]

As with NK cell infusions for leukemia, there are multiple cell types that can be used for the generation of CAR-NK cells.[163] Peripheral blood CD56+ NK cells can be obtained through apheresis, depleted of T and B cells, and expanded in a stimulatory environment. These NK cells possess a mature phenotype and effectively eliminate tumor cells but exhibit low proliferation. Lymphocytes derived from umbilical cord blood have a high proportion of NK cells of an immature phenotype that exhibit reduced expression of CD16, perforin, and granzyme B. However, their proliferative capacity is much greater than that of NK cells derived from peripheral blood.[221] iPST-derived CAR-NK cells exhibit a high proliferative capacity but have low levels of CD16 and KIR and high levels of inhibitory NKG2A. These deficits can be rectified via insertion of missing cytotoxic components. Also, the NK-92 cell line can be genetically modified to express a CAR molecule and then infused following irradiation. Low expression of KIR and CD16 by this cell line is a limiting factor.

NK cells are notoriously resistant to viral transduction with retrovirus- or lentivirus-based constructs. The use of modified viral vectors, cationic transfection reagents, and cytokine activation can help improve the transduction efficiency. Electroporation can result in a high rate of gene uptake; however, stable integration of the construct is not possible and consequently there is transient expression of the CAR construct. The use of transposon technology and clustered regularly interspaced short palindromic repeats (CRISPR)/Cas9 systems in conjunction with electroporation or viral approaches can improve the efficiency of gene uptake and dictate the site of integration.[220]

Expansion of the NK cell product pre-infusion can be achieved with various combinations of cytokines, and these can be chosen with the goal of directing the NK cell population toward a particular phenotype, such as the use of IL-12, IL-15, and IL-18 to induce a memory NK cell.[222,223] However, if high concentrations of these factors are used there is the potential for cytokine addiction and reduced in vivo efficacy. Genetically engineered feeder cells represent an alternate method for driving the expansion of NK cells. NK cells have a limited ability to proliferate, and unlike T cells, infused NK cells cannot be detected in a patient's circulation past 1 to 2 weeks post-transfusion. For this reason, the systemic administration of IL-2 or IL-15 has been considered as a means of lengthening the time frame of CAR-NK cell activity. The delivery of CAR-NK constructs in combination with anti-tumor mAbs, checkpoint inhibitors, and targeted drugs to eliminate immune suppressor cells is being investigated.

FUTURE DIRECTIONS

Rapid secretion of powerful immunomodulatory cytokines and chemokines supports the role of NK cells as "first responders" to immune insults and foreign invaders, facilitating mobilization and tailoring of the innate and adaptive immune responses. Potent natural cytotoxicity, unrestricted by the need for classical antigen presentation and costimulation required for adaptive immune cells suggest that NK cells have an important, complementary role to that of cytotoxic T lymphocytes. Further understanding of NK cell biology will certainly shed more light on the therapeutic potential for NK cells in the treatment of human disease.

CHAPTER 22

B-CELL DEVELOPMENT

Kenneth Dorshkind, Dinesh S. Rao, and David J. Rawlings

B lymphocytes are the subset of white blood cells specialized to synthesize and secrete immunoglobulin (Ig). Their name derives from the finding that the avian *b*ursa of Fabricius is a site of B-cell production. However, post-natal B-cell production in mammals takes place in the bone marrow. Following their production, newly generated B lymphocytes migrate into secondary lymphoid organs such as the spleen where they undergo final maturation. Mature B cells may remain there or relocate via the circulation to additional tissues such as lymph nodes where they are poised to respond to antigenic challenge.

This chapter focuses on adult B-cell development and the regulation of that process, although we briefly discuss fetal B lymphopoiesis. We then outline B-cell maturation in secondary lymphoid tissues. The information presented provides a basis for understanding abnormalities of B-cell development such as leukemia, lymphoma, and immunodeficiency states. Although we emphasize the human literature as much as possible, frequent reference to findings in mice are made as studies in that species have contributed much to what is known about B-cell development.

STAGES OF B-CELL DEVELOPMENT

As a result of advances in the development of monoclonal antibodies to leukocyte cell surface antigens and flow cytometry, it is possible to resolve various stages of murine and human B-cell development from the hematopoietic stem cell (HSC) to newly produced, surface IgM expressing B cells.

Murine B-Cell Development

As the progeny of murine HSCs differentiate, they generate multipotent progenitors (MPPs). MPPs include four phenotypically separable subsets; MPP1s are short-term HSCs, MPP2s and MPP3s are myeloerythroid biased, and MPP4s primarily generate lymphoid progeny. MPP4s are presumably the precursors of most lineage-negative (Lin^-) $\mathrm{CD117(c\text{-}kit)}^{\mathrm{low}}$ $\mathrm{Sca\text{-}1}^{\mathrm{low}}$ $\mathrm{CD127}^+$ (interleukin-7 receptor α) common lymphoid progenitors (CLPs). Lin^- indicates that the cells lack expression of determinants present on mature myeloid, erythroid, and lymphoid lineage cells. CLPs then mature through pre-pro-B, pro-B, pre-B-, and B-cell stages of development that can be phenotypically resolved based on their expression of various cell surface and cytoplasmic determinants (Fig. 22.1). The stages of development depicted in Fig. 22.1 are based on the scheme originally defined by Hardy.[1]

Human B-Cell Development

The human MPP compartment is not as well defined as in the mouse, but various downstream stages of development which parallel those in the mouse can be phenotypically identified.[2] For example, CLPs sequentially generate pro-B, pre-B, and B cells each of which expresses distinct combinations of cell surface determinants.[2–4] Fig. 22.1 shows that human pre-B and newly produced B cells express CD20. It is relevant to note this determinant because antibodies that recognize it (rituximab) are in widespread clinical use for the treatment of lymphoma and, increasingly, autoimmune diseases. Developing and mature B-lineage cells express additional cell surface determinants that include CD21, CD22, CD24, CD38, and CD40, several of which are linked to critical intracellular signaling pathways.

B LINEAGE SPECIFICATION AND COMMITMENT

As differentiation of HSCs and immature precursors into the B lineage occurs, genetic programs that promote B lymphopoiesis are activated while those used by non-B lineage cells are silenced. This results in *specification* of progenitors toward the B-cell lineage. For example, cells at the CLP stage of development are destined to generate B cells, but they retain limited T and myeloid potential. Because of this, CLPs can be thought of as B lineage *specified*. However, pro-B cells only generate B lymphocytes and are B lineage *committed*. Specification and commitment are dependent on the interdependent expression of a cascade of transcription factors and other regulatory molecules in developing B lineage cells.[5]

Transcriptional Regulation of B-Cell Development

The generation of lymphoid cells from HSCs is dependent on expression of the Ets family member PU.1. Mice in which *Spi1*, the gene encoding PU.1, is not expressed produce erythroid and megakaryocytic but not monocytic, granulocytic, and lymphoid cells and die during the fetal or neonatal period. PU.1 regulates several events that promote B lineage specification, including expression of CD135 (Flt3), which is expressed on immature progenitors such as the CLP, CD45R(B220), and CD127 (IL-7Rα). However, deletion of *Spi1* at the CLP stage of development has no negative effect on B-cell development, indicating that PU.1 expression is not required once B-cell specification has initiated.

Further B lineage specification is dependent on expression of additional transcription factors including early B-cell factor (EBF) and the E2A-encoded splice variants E12 and E47. Each of these DNA-binding proteins regulates the expression of a variety of B-lineage target genes. For example, Ebf1 regulates the expression of Igα, VpreB, λ5, and Pax5 and represses genes associated with alternative lineage fates. Mice in which EBF and E2A are not expressed exhibit an almost complete block in B-cell development at the pro-B-cell stage.

Ebf1 and E2A-expressing progenitors can still exhibit some non-B lineage potential, indicating that the expression of these DNA binding proteins does not result in absolute B lineage commitment. Instead, this is dependent on expression of the Pax5 transcription factor.[6] Phenotypically identifiable B-cell precursors are present in *Pax5* knock-out mice, and these cells can differentiate into myeloid, T, and natural killer (NK) cells. However, if the gene encoding Pax5 is introduced into *Pax5*-deficient precursors, this developmental promiscuity ceases. Thus, a critical function of Pax5 is to suppress non-B lineage potential. For example, Pax5 may repress expression of myeloid growth factor receptors and inhibit T-cell potential by antagonizing expression of Notch1, a cell-surface receptor required for commitment to the T-cell lineage. Continued Pax5 expression is necessary to maintain lineage fidelity even in relatively mature B cells.

Additional transcription factors, such as Ikaros, Satb1, Foxo1, IRF4, IRF8, c-Myb, Gfi1, Miz-1, Bcl6, and Bach2, function at various times during B-cell development. For example, IRF4 is involved

with Ig recombination and the attenuation of IL-7 signaling, thus promoting the transition from the pre-B to B cell stages of maturation. IRF8, along with PU.1, regulates EBF expression. Ikaros plays a role in regulating expression of key B lineage genes such as IL-7Rα and EBF and promoting B lineage commitment. c-Myb has been shown to synergize with PU.1 to activate IL-7 receptor (IL-7R) gene transcription. Focused reviews should be consulted for a full discussion of these and additional transcriptional regulators of B lymphopoiesis.

MicroRNAs

MicroRNAs (miRNAs) are 19 to 23 nucleotide-long RNA molecules that are processed from longer RNA precursors. miRNAs act post-transcriptionally, by promoting degradation of mRNA targets or by blocking their translation. However, like transcriptional regulators, a single miRNA can potentially regulate many targets to provide coordinated and simultaneous regulation of a network of genes.

Mice with conditional deletion of Dicer, an enzyme necessary for miRNA synthesis do not develop B lymphocytes, indicating the importance of miRNA regulatory mechanisms during B-cell differentiation. Work is now ongoing to identify the role of specific miRNAs at distinct stages of B-cell development. For example, deletion of miR-17∼92 cluster blocks pro-B-cell maturation.[7]

IMMUNOGLOBULIN GENE REARRANGEMENT

The defining feature of a B lymphocyte is the expression of cell surface Ig, which is formed by two heavy chains and two light chains, each of which is encoded by multiple gene segments. The process of Ig gene rearrangement occurs in a step-wise manner as murine and human B cells mature through the cellular stages of development just described.[8,9]

Heavy Chain Gene Rearrangement

The initial Ig rearrangement event occurs at the heavy chain locus located on human chromosome 14 (Fig. 22.2). The Ig heavy chain locus includes multiple variable (V), diversity (D), joining (J), and constant (C) region gene segments that are separated from one another by introns. The V region genes are located at the $5'$ end of the Ig heavy chain locus, and each consists of approximately 300 base pairs. These genes, which are separated by short intron sequences, are organized into families based on sequence homology. There are ∼25 human D region genes located $3'$ to the V region that are also grouped into families based on sequence homology. Downstream of the D region are six human J region genes. Finally, 10 C region genes representing alternative Ig isotypes are arranged in tandem.

The transcription of the unrearranged heavy chain locus occurs prior to actual Ig gene recombination. This results in production

Figure 22.2 REARRANGEMENT AND EXPRESSION OF THE HUMAN IMMUNOGLOBULIN HEAVY CHAIN GENE. The figure shows the Ig heavy chain gene and the signal sequences 3′ of each V region locus, 5′ and 3′ of each D region locus, and 5′ of each J region locus. These consist of heptamer and nonamer sequences separated by either 12 or 23 base pairs. During immunoglobulin (Ig) recombination, a signal sequence of 12 base pairs can only join to another of 23 base pairs (the so-called 12–23 rule). The initial heavy chain gene rearrangements form coding joints between D and J regions as well as signal joints that are ultimately degraded. Subsequently, the joining of the V region gene to the DJ complex occurs. After a successful rearrangement, the VDJ complex, the μ intron, and portions of the constant regions are transcribed. RNA processing and differential splicing results in formation of an mRNA molecule that is then translated. In the example shown, the rearranged VDJ complex and the constant region, with the μ and δ C region genes, is transcribed. After RNA processing and translation, a particular B cell could then express μ protein, δ protein, or both.

of developmentally regulated transcripts of unrearranged Ig genes, referred to as germline or sterile transcripts. Multiple species of sterile transcripts have been described, and some could conceivably encode proteins. A mechanistic link between transcription and Ig gene rearrangement has been hypothesized. For example, transcription could make unrearranged Ig genes accessible to both RNA polymerase and V(D)J recombinase, the germline transcripts could function in the rearrangement reaction, or transcription could alter structural characteristics of DNA, making the recombination signal sequences described below better targets for recombination.

The initial event during heavy chain gene rearrangement occurs by the CLP stage and juxtaposes a D region segment to a J region segment. Although in theory any D region gene can join with equal frequency to any J region gene, there may be preferential utilization of selected D and J region genes at various times during fetal and adult B-cell development. The next recombination event involves the rearrangement of a V region gene to the D–J complex, and this occurs at the pro-B-cell stage of development. The biased usage of J proximal V genes may occur in the newly generated repertoire of neonatal mice and humans. The heavy chain C region remains separated from the rearranged VDJ complex by an intron, and this entire sequence is transcribed. RNA processing subsequently leads to deletion of the intron between the VDJ complex and the most proximal C region genes. After translation, μ heavy chain protein is expressed in the cytoplasm of pre-B cells (see Fig. 22.2).

The E2A encoded transcription factors are particularly important for Ig gene recombination and mediate their effects via binding to specific promoter sequences located 5′ of each heavy chain V region and enhancer regions located 3′ of the J region genes and downstream from the CH region genes (see Fig. 22.2). Before Ig gene rearrangement, E12 and E47 proteins may be in an inactive state owing to their heterodimeric association with another protein known as Id. Successful transition from the pro-B to pre-B-cell stage is dependent on cessation of Id expression, a conclusion consistent with the fact that mice expressing an Id transgene have a complete block in B-cell differentiation.

Each pro-B cell has two Ig heavy chain genes, but only one of these encodes heavy chain protein in any given cell. This phenomenon is known as allelic exclusion. One theory for how this occurs is that functional Ig rearrangements are rare, so the chance that two functional rearrangements will occur in an individual cell is extremely low. Alternatively, the expression of heavy chain protein from a successfully rearranged allele may inhibit rearrangements at the other heavy chain allele.

Light Chain Gene Rearrangement

Ig light chain protein can be encoded by the kappa (κ) or lambda (λ) genes. Greater than 90% of murine B cells express κ protein. However, the proportions of human κ and λ proteins are more equivalent, with approximately 60% of human B cells expressing κ light chain protein.

The human κ gene is located on chromosome 2 and includes around 40 Vκ region genes, five functional Jκ region genes, and one C κ region gene. The human λ locus is located on human chromosome 22. Approximately 30 human Vλ genes exist. There are seven human Cλ genes, four of which are functional and three of which are pseudogenes. Each Cλ gene is located 3′ of a respective J λ gene. Light chain genes do not include D region loci.

The initial event in light chain gene recombination involves the joining of a V region to a J region. The VJ complex remains separated from the light chain C region by an intron, the entire complex is transcribed, and further splicing of the intron results in formation of a mature V–J–C transcript. Light chain rearrangements in mice occur initially at the kappa locus. If rearrangements at the first κ allele are unsuccessful, attempts are made to rearrange the second κ gene, and the λ locus is used if this fails.

The Immunoglobulin Recombinatorial Machinery

Ig heavy and light chain gene rearrangements are dependent on enzymes that delete intronic sequences and join coding segments of DNA. The enzymes that mediate these functions act by recognition of recombination signal sequences located 3′ of each heavy chain V region exon, 5′ of each heavy chain J segment, and 5′ and 3′ of each heavy chain D region gene (see Fig. 22.2). Each recombination signal sequence consists of conserved heptamer and nonamer sequences separated by nonconserved DNA segments of 12 or 23 base pairs. During Ig gene recombination, these recognition sequences form loops of DNA, which in turn bring the coding exons in apposition to one another. These noncoding loops are subsequently deleted and degraded.

The expression of two highly conserved proteins, referred to as recombinase-activating genes-1 (RAG-1) and RAG-2, is required for heavy and light chain gene recombination,[8,9] and failure to express *Rag* results in a complete block in B- as well as T-cell development. Results from cell-free systems that measure V(D)J recombination indicate that RAG proteins are involved in cleavage of DNA at recombination signal sequences and the subsequent joining of coding sequences to one another. In addition to the RAG proteins, general DNA repair enzymes, such as those encoded by the Ku complex of genes, also play a critical role in Ig gene recombination.

Generation and Selection of the Primary B-Cell Repertoire

Each newly generated B cell expresses Ig with a specific antigen binding capability. Thus, humoral immunity is dependent on the production of a large number of B cells to ensure that a B lymphocyte capable of responding to a particular antigenic challenge is present. Several mechanisms have evolved to ensure that B cells with a diverse Ig repertoire are generated.

First, heavy and light chain proteins are encoded by multiple germline V, J, and, in the case of the heavy chain, D region genes, and the combinatorial diversity among them is enormous. Second, nucleotides not encoded in the germline can be added to D-J and VDJ junctions by a nuclear enzyme known as terminal deoxynucleotidyl transferase (TdT). Third, DNA joints that form during recombination are often imprecise and can occur at any of several nucleotides in the germline. Although out-of-frame joints that cannot be transcribed may result, this junctional diversity has the potential to generate different amino acid sequences, resulting in added diversity of the Ig repertoire. Finally, somatic mutation of V region genes can occur, usually in secondary lymphoid tissues. This latter process, which results in an increased affinity of the antibody for antigen, is discussed in more detail in the section on secondary B-cell development.

Because the process of Ig gene recombination is random, self-reactive B cells may be produced, and several mechanisms have been proposed to account for their fate. In some cases, the presence of self-antigen may not activate self-reactive B cells. This scenario may result from weak B-cell affinity for the antigen or the autoantigen may be present at an extremely low concentration. In other instances, interaction of antigen with the autoreactive B cell may result in anergy. The level of membrane Ig on anergic B cells may be reduced up to 20-fold, the cell's ability to proliferate may be impaired, and differentiation into Ig-secreting cells may be blocked. Finally, self-reactive B cells may be clonally deleted. Clonal deletion may result from cytolysis by other cells, such as BM macrophages, or autoreactive B cells may undergo a physiologic change resulting in cell death after receptor engagement.[10]

The recognition of self-antigen by a B cell may not necessarily result in anergy or deletion but instead may lead to receptor editing. In this process, rearranged κ light chain alleles can be replaced by secondary rearrangements of upstream Vκ genes to downstream, unrearranged Jκ segments. These secondary rearrangements, which may delete the primary VκJκ complex or separate it from Cκ by inversion, are possible because of the continual presence of unrearranged Vκ regions upstream of the joined VκJκ coding segments.

THE PRO-B- AND PRE-B-CELL CHECKPOINTS

B-cell progenitors progress through two critical checkpoints as they mature into B lymphocytes. The first occurs at the pro-B- to pre-B-cell transition. The second transition occurs as pre-B cells mature into B cells.

The Pro-B- to Pre-B-Cell Transition

The key event during the pro-B- to pre-B-cell transition is the rearrangement and expression of Ig heavy chain genes. Ig heavy chain gene rearrangements are productive in only around one-third of pro-B cells, so the majority of pro-B cells do not navigate this transition. Those cells with nonproductive Ig gene rearrangements undergo apoptosis and are eliminated from the BM by resident macrophages and stromal cells.

However, if Ig heavy chain recombination is productive and μ heavy chain protein is expressed, it appears on the surface of the pre-B cells in association with two additional molecules referred to as the surrogate light chains. The surrogate light chain proteins, Vpre-B and λ5, are encoded by genes located on chromosome 16 in mice and on chromosome 22 in humans and are non-covalently linked to one another. λ5 in turn is covalently linked to the CH1 domain of the μ heavy chain via a carboxyl-terminal (C-terminal) cysteine. One role of the surrogate light chains is to select heavy chains that will ultimately be capable of pairing with conventional light chains.[11] If this does not occur, then these cells will likely be deleted.

The μ heavy chain-surrogate light chain complex is additionally associated with two transmembrane proteins, Igα (CD79a) and Igβ (CD79b), and the entire complex is referred to as the pre-B-cell receptor (*pre-BCR*). The intracellular tails of both Igα and Igβ contain immunoreceptor tyrosine activation motifs (ITAMs) critical to the signaling function of the pre-BCR (Fig. 22.3, *upper panel*). Lipid rafts that contain mediators of intracellular signaling such as Lyn are constitutively associated with the pre-BCR in human pre-B cells. Cross-linking of the pre-BCR leads to an increase in Lyn kinase activity, phosphorylation of the Igβ chain, and recruitment and activation within the pre-BCR complex of additional signaling intermediates, including spleen tyrosine kinase (Syk), B-cell linker protein (BLNK), phosphoinositide-3 kinase (PI3K), Bruton's tyrosine kinase (Btk), VAV, and phospholipase C-γ (PLCγ2). These events lead to calcium flux and activation of signaling cascades within the pre-B cell (see Fig. 22.3, *lower panel*).

These signaling pathways are crucial in developing pre-B cells. One of the best examples of this requirement is the prototypical humoral immunodeficiency, X-linked agammaglobulinemia (XLA). XLA results from mutations within the gene segments that encode the nonreceptor tyrosine kinase, Btk. In males who express a defective Btk protein, pre-B-cell clonal expansion is markedly depressed, and there is an almost complete loss of immature B cells in the BM and in secondary lymphoid organs. As a result, affected males develop recurrent bacterial infections early in life because of a profound decrease in circulating Ig. A nearly identical clinical phenotype has been observed in persons with mutations in additional components of the pre-BCR signaling complex, including the μ–heavy chain, λ5, Igα, Igβ, the key B-cell adaptor protein BLNK, and the lipid kinase PLCγ2.

How signaling through the pre-BCR is initiated is unclear. It has been suggested that this occurs by binding of the extracellular portion of the pre-BCR to an environmental ligand. The identification of such ligands has been difficult, although galectin-1 has been suggested to function in this capacity. It has also been proposed that constitutive signaling occurs after pre-BCR surface expression. Structural studies which suggest that the pre-BCR constitutively assembles as an oligomer provide a potential mechanism for this behavior.[12]

The Pre-B to B-Cell Transition

Pre-BCR expressing cells undergo several rounds of proliferation in response to the stromal cell derived cytokine IL-7, and this expands the size of the clone that expresses a particular μ heavy chain. However, IL-7R signaling inhibits *Rag* gene expression. Thus, in order to reactivate the recombinatorial machinery and initiate light chain gene recombination, downregulation of the IL-7 response must occur.[13] There is general agreement that this is accomplished by movement of pre-BCR expressing cells from IL-7 high to IL-7 areas of the bone marrow.

Different mechanisms for how this is achieved have been proposed, but one current model is that pre-B cells are more motile compared to pro-B cells and thus spend a reduced amount of time in contact with IL-7 producing stromal cells (Fig. 22.4).[14] This occurs because, in contrast to pro-B cells that tightly adhere to stromal cells via expression of adhesion molecules that include focal adhesion kinase (FAK) and very late antigen 4 (VLA-4), these receptors are expressed at lower levels of pre-B cells which thus allows them to move away from the IL-7 secreting cells. As a result, IL-7R signaling is attenuated and pre-BCR signaling predominates. This represses proliferation, likely through activation of the RAS–extracellular-signal-regulated kinase (ERK) pathway as well as via limiting PI3K activity through BLNK mediated signals leading to expression of transcription factors, including E2A, IRF4, and PAX5, that induce cell cycle exit, RAG expression and light chain gene recombination (see Fig. 22.4).[13] As with heavy chain recombination, functional light chain gene rearrangements do not occur in all pre-B cells. However, when they are successful, the heavy and light chains assemble and are expressed on the surface of a newly produced B lymphocyte as the mature B-cell receptor (BCR).

Events that disrupt the pre-B-cell transition such as activating lesions in IL7 receptor subunits or downstream mediators significantly enhance the risk for development of pre-B acute lymphoblastic leukemia. An improved understanding of these changes will likely provide new therapeutic targets to inhibit leukemia cell growth.[15]

The B-Cell Receptor

Once light chain expression occurs, a complete Ig molecule is expressed on the surface of newly produced B cells. These cells express IgM, but others may co-express cell surface IgD. This occurs because the primary heavy chain transcript includes the rearranged VDJ heavy chain complex, the μ and δ C regions, and the intron separating these exons. If RNA processing results in association of the Cμ region with the VDJ complex, the B cell expresses IgM. Alternatively, if the Cμ exon is deleted along with the heavy chain intron, the VDJ complex and the Cδ exon become contiguous and the B cell expresses IgD.

The complex of cell surface Ig, along with Igα and Igβ, is referred to as the *BCR* (see Fig. 22.3). The cytoplasmic tail of the Ig heavy chain is relatively short, and, as noted above, both Igα and Igβ contain an ITAM in their intracellular tails that is required for signal transduction following antigen binding to the BCR. Antigen engagement initiates assembly of a lipid raft, BCR-associated "signalosome," composed of multiple signaling molecules that include tyrosine kinases, serine/threonine kinases, lipid kinases, lipases, phosphatases, and linkers and adaptors. This signalosome mediates a cascade of intracellular signals that includes the initiation of calcium influx. Additional calcium-dependent and -independent downstream signals that include the mitogen-activated protein (MAP) kinase cascade (c-jun N-terminal kinase [JNK], p38, ERK) and activation of key transcription factors that include JUN, c-fos, nuclear factor of activated T cells (NFAT), and nuclear factor kappa-light-chain enhancer of activated B cells (NF-κB) in turn mediate transcriptional events leading to cell proliferation, survival, and differentiation. The level and duration of receptor activation and hence transcriptional output are further modified by a series of cell surface co-receptors or "response modifiers" that bind to complement or to receptors on the surface of stromal cells, activated T cells, or other populations present in secondary lymphoid organs.

THE HEMATOPOIETIC MICROENVIRONMENT

Hematopoiesis takes place in the intersinusoidal spaces of the medullary cavity in association with several types of hematopoietic and non-hematopoietic cells that together form the hematopoietic microenvironment (see Fig. 22.4). These populations include mesenchymal stromal cells, adipocytes, osteoblasts, sympathetic nervous system fibers, and endothelial cells.[16]

Figure 22.3 THE PRE-B-CELL RECEPTOR AND B-CELL RECEPTOR AND ASSOCIATED SIGNALING INTERMEDIATES. *Top*, μ heavy chain protein in pre-B cells is associated with the surrogate light chains v-pre-B and λ5 *(left)* to form the pre-B-cell receptor (pre-BCR). In newly produced B lymphocytes, μ heavy chain is associated with conventional light chains *(right)* to form the BCR. Associated with heavy chain in both pre-B and B cells are two additional transmembrane proteins, Igα and Igβ, that contain immunoreceptor tyrosine activation motifs (ITAMs) critical to the signaling function. *Bottom*, Expression of the pre-BCR (or possibly its binding to a stromal ligand) or binding of antigen to the mature BCR, respectively, initiates the assembly of a lipid raft, BCR-associated "signalosome" composed of multiple signaling molecules, ultimately leading to transcriptional events that promote cell proliferation, survival, and differentiation. *ERK*, Extracellular-signal-regulated kinase; *Ig*, immunoglobulin; *JNK*, Janus kinase; *NF-κB*, nuclear factor kappa-light-chain enhancer of activated B cells; *NFAT*, nuclear factor of activated T cells; *SHIP*, src homology 2-containing inositol phosphatase; *SHP*, src homology 2-containing protein tyrosine phosphatase.

Several cell surface determinants, some of which have been introduced above, mediate adhesion between developing B lineage cells and stromal cells. Both murine and human pre-B cells express the VLA-4 integrin that interacts with a stromal cell ligand identified as vascular cell adhesion molecule-1 (VCAM-1). Pro- and pre-B cells also express varying amounts of FAK involved in stromal cell binding via mediation of integrin signaling. FAK is an intracellular kinase typically linked to surface integrins. The hematopoietic microenvironment is also a source of cytokines that regulate B lymphopoiesis and include CXCL12 (SDF1), Flt3 ligand, Stem Cell Factor, IL-7, Wnt family members, TGF-β family members, and thymic stromal lymphopoietin (TSLP).

A full discussion of the cytokines that regulate B-cell development is beyond the scope of this chapter, but the focus can be narrowed when only those with obligate effects on B-cell development are considered. The critical B lymphopoietic cytokine in mice is IL-7, which

Figure 22.4 THE HEMATOPOIETIC MICROENVIRONMENT. (A) Cross-section of bone showing elements of the medullary circulation and the marrow sinusoids. Stromal cells that support developing blood cells are located in the intersinusoidal spaces. (B) Pro-B cells are tightly adherent to IL-7 producing stromal cells via their expression of adhesion molecules such as focal adhesion kinase and vascular cell adhesion molecule-1. Following the successful expression of Ig μ heavy chain and assembly of the pre-B-cell receptor (pre-BCR), pre-B cells must ultimately attenuate IL-7 receptor signaling in order to recombine Ig light chain genes and mature into BCR expressing B lymphocytes. A current model proposes that they are less adherent to stromal cells compared to pro-B cells and as a result migrate away from IL-7 rich areas. This results in attenuated IL-7 receptor signaling while pre-BCR signaling in these cells induces cell cycle exit, RAG expression, and light chain gene recombination. *(A, From Dorshkind K. Regulation of hematopoiesis by bone marrow stromal cells and their products. Annu Rev Immunol. 1990;8:111. Reprinted by permission from the Annual Review of Immunology. B, Based on concepts reviewed and depicted in reference 14.)*

binds to the IL-7R.[17] IL-7 signaling potentiates the recombination of a VH region gene segment to an already rearranged DJH complex and, as discussed above, is critical for pro-B-cell proliferation which expands the size of clones expressing a particular Ig heavy chain.

The IL-7R is formed by the IL-7R α chain and the common cytokine γ chain. The Janus kinases (JAK) JAK3 and JAK1 are associated with the γc and IL-7 Rα, respectively and are critical for IL-7R mediated signaling. When IL-7 binds to the IL-7R, these JAK kinases are phosphorylated, and this in turn recruits signal transducer and activator of transcription 5 A (STAT5A) and STAT5B. The STAT molecules can then translocate to the nucleus where they act as transcriptional activators. The requirement for IL-7 in murine B-cell development is demonstrated by studies showing a block in B-cell development at approximately the pro-B-cell stage in IL-7 and IL-7R knock-out mice.

The precise role of IL-7 during human B-cell development is unclear. Human CD34$^+$CD19$^+$ pro-B cells proliferate in response to IL-7, but human B-lymphopoiesis may not be dependent on IL-7, because B cells are present in patients whose B-lineage cells express a mutated IL-7Rα chain. In addition, B cells are present in patients with X-linked severe combined immunodeficiency; these individuals have mutations in the gene encoding the cytokine common γ chain, which is part of the receptor for IL-7.[18]

FETAL B-CELL DEVELOPMENT

Most knowledge of fetal hematopoiesis is based on studies in mice. It has been long recognized that some blood cells in that species are generated prior to the appearance of HSCs in an early wave of hematopoiesis that occurs in tissues such as the yolk sac. It has been thought that this pre-HSC wave of development is restricted to the production of erythroid and selected myeloid cells, but there is strong evidence that innate-like B-1 and γδ T cells are also generated.[19] The contribution of B cells generated in this pre-HSC phase to the adult immune system remains to be determined. HSCs are generated at embryonic day 10.5 of murine gestation, and their B lineage progeny can be detected several days thereafter in fetal liver, bone marrow, and spleen.

Hematopoiesis initiates in the human yolk sac at 3 weeks of gestation, pre-B cells are present in human fetal liver by week 8 of gestation, and surface IgM$^+$ cells are detectable at week 9. IgM expressing cells have also been observed in additional human fetal tissues that include the omentum, the peritoneal cavity, and the spleen. Studies of human fetal B-cell development are limited and this is an area in need of further investigation.

B-1 B Cells

The B cells produced in adult BM, which constitute the majority of B cells in spleen and lymph nodes, are referred to as B-2 B cells. This nomenclature serves to contrast them with another functionally distinct population of mature B cells termed B-1 B cells. B-1 B cells are best characterized in mice where they constitute around 5% of total B lymphocytes. Murine B-1 B cells preferentially localize in serous cavities and in those sites can be distinguished by their unusual phenotype that includes high levels of sIgM, low levels of sIgD, and expression of CD11b, a determinant typically expressed on myeloid cells. B-1 B cells can be further subdivided into B-1a B cells that are CD5$^+$ and B-1b B cells that do not express this determinant. Antibodies from B-1 B cells, at least in mice, are required for protection against pathogens such as *Streptococcus pneumoniae*.

Mouse B-1 B cells are generated most efficiently from precursors that arise in the fetus.[20] Thus, while HSCs from fetal liver can efficiently generate both B-1 and B-2 B cells, those from the adult primarily produce B-2 B lymphocytes. These observations support the long-held view that B-1 cells are a distinct B-cell lineage preferentially derived from fetal precursors. The description of a phenotypically identifiable B-1 B-cell–specified progenitor that is preferentially generated in the fetus provided strong support for this view.

The regulation of B-1 and B-2 development is distinct, providing further support for the conclusion that these are distinct B-cell populations. For example, while B-2 B-cell development is blocked in IL-7 deficient mice, B-1 development can occur. The preferential generation of B-1 B cells from fetal progenitors has been linked to the expression of the Lin28b miRNA binding factor by fetal HSCs and B lineage progenitors. Adult HSCs are Lin28b$^-$, but ectopic Lin28b expression in adult hematopoietic stem/progenitor cells results in their ability to generate B-1 B cells, and B-1a B cells in particular.[21]

B-1a B cells in mice are CD5$^+$, and many studies have claimed to have identified human B-1 cells based on their simultaneous expression of CD5 and sIgM. These reports must be viewed with caution because CD5 is not a B-1–restricted determinant. The identification of B-1 B cells in humans has proven elusive, but a CD20$^+$ CD27$^+$ CD43$^+$ CD70$^-$ population of cord blood B cells that has properties consistent with their being classified as human B-1 cells has been described.[22] The further characterization of human B-1 B cells and studies to define their origin remain areas of active investigation.

SECONDARY LYMPHOID TISSUES

The bone marrow and the thymus are the sites of primary, antigen-independent lymphocyte development and are distinguished from secondary lymphoid organs that include the spleen, lymph nodes, and epithelial and mucosa-associated lymphoid tissues such as Peyer patches in the small intestine. Secondary lymphoid tissues are the sites of B-cell maturation and the initiation of humoral immune responses.

Anatomic Organization of Secondary Lymphoid Tissues
